PREFACE TO THE REVISED EDITION

I

THE world of photography has changed more and faster during the last ten years than in any other decade of its history.

As it has become cheaper and easier to make better pictures, the use of the camera—one of the symbols of contemporary social evolution—has spread to new masses.

Professional photography has equally grown in dimension and scope serving commerce and industry. News photography is now an ever-present witness to events everywhere.

Photographic materials provide the most efficient means of recording and documentation in nearly all fields of business and professional activity. Contemporary reproduction and printing are unthinkable without them. New methods of education and tools of perception are based on their use.

Photography helps in pioneering research far beyond the limitations of sight. Cameras observe, isolate and interpret; they hold on to passing time, vary its pace and look into the unknown.

Photography, which used to mean just "taking pictures", now provides the most penetrating and all-embracing medium of communication and understanding by images.

New aims call for new means as in turn new means will point to new ends.

Sensitized materials which serve photography are now undergoing fundamental changes. They are no longer based solely on silver halide systems. Alternative mechanisms provide and evolve altogether new technologies and economic requirements of their own.

Not surprisingly, the dimensions, structure, and geography of the industries producing the new equipment and materials are appreciably affected by all that.

2

THE FOCAL ENCYCLOPEDIA OF PHOTOGRAPHY was first published October 1956; it was reissued with minor corrections eleven times within nine years.

To keep step with the developments in photography, not only was a major revision in depth and breadth inevitable—but it had to be envisaged on almost the same scale as the original production of the book. This work commenced early in 1962 and continued into July 1965.

Every effort has been made to ensure as lasting an expectation of usefulness for the Revised Edition as the First Edition proved to possess. The Editors were as much concerned with the question of what to include as with the balancing problem of what to reject. They were careful to account for progress as distinct from mere novelty. Similarly they were concerned with preserving information which may appear to be obsolescent but is basic to understanding.

3

Any revision of a reference work must be guided by the present needs of its users.

The changes that have come over photography pointed first of all to the need for paying particular attention to the new technologies, the new subjects to which they are applied and the new terminology which has thus emerged. By far the largest part of the new text that has gone into the Revised Edition had to be devoted to them.

A rising level of education also called for providing in depth factual material of a type which readers so often look for in reference books. A fair amount of additional historical, statistical and geographical information has been included for this purpose.

Thus whilst the spirit of the work has not changed, with the spread of the contents into new areas some shift of balance became inevitable as the text had grown from 1,300,000 to 1,700,000 words, and the number of illustrations from 1,500 to 1,750. The Revised Edition is one-third larger than the First Edition was.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

4

The initiative and control of the revisions was largely in the hands of the Principal Technical Editor; the organization of the formidable amount of work rested with the Administrative Editor. Their efforts were aided by several new consultants, notably in the fields of colour, economics, education, science and techniques.

All contributors to the First Edition were invited to revise their original contributions and, whenever they were not in a position to do so, alternative experts were coopted. Their signatures were added (in brackets) to those of the contributors of the original articles to denote collective responsibility.

Articles devoted to the national aspects of photographic activities have been extended to cover recent developments and achievements. Their number has grown to twenty-eight.

Nearly one hundred new biographies have also been added.

The number of contributors—including authors of new articles and the revising experts—in the Revised Edition has grown from 197 to 276.

ABERRATIONS OF LENSES

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

A perfect lens would show the image of a point as a point, and a straight line as a straight line. But in practice, lenses are never perfect; they reproduce a point as a patch, and a straight line as a more or less curved band. Most of the trouble is caused by faults, or aberrations, inherent in the lens construction.

The designer controls most of the aberrations by combining a number of single lenses in such a way that the aberrations of one lens tend to be cancelled out by opposing aberrations in the others.

Aberrations which affect an image point on the axis of the lens are classified as axial aberrations. The principal axial aberrations are chromatic and spherical.

Chromatic Aberration. A prism deviates blue light more than red light. Simple lenses do the same thing with the result that blue light comes to a focus nearer to the lens than red light. This defect is called the chromatic aberration of the lens. The human eye is most sensitive to the light towards the middle of the spectrum, but some photographic emulsions are most sensitive to light at the blue end. So while a lens suffering from chromatic aberration may form an image that looks sharp, it gives a blurred, out-of-focus negative.

CHROMATIC ABERRATION. A simple lens refracts blue rays A more strongly than green rays B or red rays C The latter therefore come to a focus farther behind the lens, and the image shows reddish-bluish colour fringes.

To obtain any correction at all it is necessary to utilize different types of optical glass in one lens system. Unfortunately the characteristics of the optical glass available today are such that complete correction for all colours is impossible and the situation is aggravated by the fact that the balance of other aberrations, particularly spherical aberration, varies with the colour of the light. In many instances the best chromatic correction of a narrow bundle of rays close to the lens axis has to be sacrificed in order to obtain a better compromise correction over the whole lens aperture and this compromise correction may become unbalanced when the aperture is reduced by several stops.

Spherical Aberration. Rays coming from an object on the axis and going through the centre of the lens come to a focus at a certain point on the axis of the lens. Rays from an axial object going through the lens near the edges should come to a focus at the same point, but in practice, because of spherical aberration, they tend to come to a different point of focus. The difference between these focal points is the spherical aberration of the lens.

When the lens is more complex in construction it is possible to correct this aberration for

SPHERICAL ABERRATION. With a simple converging lens the rays farthest from the lens axis converge more strongly, and come to a focus nearer the lens than the central rays close to the lens axis. The image is never fully sharp.

rays passing through one selected annular zone of the lens leaving rays passing through other zones to cross the axis at positions slightly different from the position where the corrected rays and a narrow central bundle of rays come to a focus. The small residual errors are called zonal spherical aberration and, in the case of a corrected lens, performance in the centre of the negative will depend on their magnitude.

Spherical aberration increases with the lens aperture.

The spherical and chromatic aberrations affect the whole of the field covered by the lens, but there are others which affect only the off-axis parts of the field. The off-axis aberrations are: coma, astigmatism, curvature of field and distortion.

Coma. This aberration is restricted to off-axis image points. In some respects it can be

SPHERICAL ABERRATION. With a simple diverging lens marginal rays appear to come from points nearer the lens.

CC-0. Agamnidhi Digital Preservation Foundation, Chandigarh

may not seriously limit the maximum aperture of the lens. With an appreciable field, the coma and astigmatism are much more important, and these—in particular, the astigmatism—increase with aperture. In practice, the maximum useful aperture of a lens is primarily controlled by astigmatism and coma.

A maximum aperture of *f*8 used to be considered good, but to-day an aperture of *f*2·8 is regarded as average, and many good fast lenses work at *f*1·5.

Off-axis aberrations increase rapidly with the angle of field and the normal photographic lens is only satisfactory for fields up to 50°. Special wide-angle lenses can cover fields of over 90° but they must work at comparatively small apertures.

Aberrations with Different Types of Lenses. The aberrations in a lens depend upon:

(*a*) the type of lens
(*b*) the skill of the designer
(*c*) the reliability and accuracy of the manufacture of the lens.

A single meniscus lens has large aberrations which are acceptable for some uses. It is easy to design and make.

A triplet lens is capable of much better performance at a larger aperture than a single meniscus lens, but design is more difficult and much greater accuracy is required during manufacture.

A lens consisting of four separated lens elements has significantly smaller aberrations than a triplet lens, but design and manufacture are more difficult.

A designer can reduce aberrations by using more complex designs, but a point is reached where the increased difficulties and errors of manufacture prevent any improvement in the reduction of aberrations.

Zoom lenses are complex mechanical—optical systems which are intended to:

(*a*) give a range of focal lengths
(*b*) have good correction for aberrations
(*c*) maintain accurate focus while zooming the lens.

These requirements are very difficult to combine and normally zoom lenses have larger aberrations than lenses of fixed focal length.

FLARE. Part of the light reaching any glass air surface in a lens is reflected back along its path. Successive reflections may direct some stray light to the film in places where it has no business to go and may even form ghost images. This is flare. A, incident light beam, producing the main image. B, light ray after one partial reflection. C, light ray after two partial reflections, forming flair.

POSITION OF LENS STOP. In a simple lens aberrations can be reduced to some extent by careful choice of the position of the stop. This determines which part of the lens forms image points due to oblique rays (i.e., inclined to the axis).

Simple Lenses. A simple lens made of a single piece of glass, generally suffers from all the aberrations described above. Even so, lenses of this type are used in the cheaper cameras and give good results. The field is made reasonably flat by giving the lens a meniscus shape and by carefully choosing the position of the stop. The effects of spherical aberration, coma, astigmatism, and field curvature are reduced by keeping the aperture down to about *f*13.

No attempt is made to correct the chromatic aberration because chromatic aberration is not a serious fault where the stop is so small and the negative is intended only for contact printing. For instance, a 4 ins. lens may have as much as 0·08 in. chromatic aberration, but this error corresponds to a circle of confusion of only 0·006-in. at *f*13, which is quite sharp enough for contact prints.

Compound Lenses. Lenses intended for making negatives for enlargment or for colour photography have to be very carefully corrected. In consequence, they are complex and more expensive than the simpler lenses in use in the early days of photography. To produce a flat field, the designer may have to accept some astigmatism and possibly a little spherical aberration—he cannot afford much or a change in aperture of the lens will shift the focus. Coma and distortion can normally be fairly well corrected; chromatic aberration can be practically eliminated for the two important colours, yellow and blue. (There remains a small degree of chromatic aberration, described as residual.) The other colours may come to slightly different foci, but the error is negligible for ordinary photography. The infra-red focus, however, is quite different from the yellow-blue focus, and when a photographic lens is to be used for infra-red photography, the mount is specially marked with the infra-red focusing position.

ABNEY, SIR WILLIAM, 1843–1920. English photo-chemist. Gave practical directions for manufacturing emulsions. Invented copper bromide-silver nitrate intensification, 1877. Introduced hydroquinone as a developer, 1880. Invented gelatin chloride printing-out paper (P.O.P.) 1882. Worked on photo-chemistry, sensitometry, densitometry, solarization, photometry, colorimetry, spectral analysis. Wrote numerous books and articles. President of the Photographic Society of Great Britain (which became "Royal" in 1894) for 5 years (1892–94, 1896, 1903–5). Received twice the Progress Medal of the R.P.S. (1878, 1890). Knighted in 1900. Was adviser in Science to the Board of Education.

ABRASION MARKS. Marks on a processed photographic material due to the effect of abrasion or milder stress either before or after exposure. Also known as pressure marks or stress marks.

Abrasion which actually tears the emulsion itself will usually result in black marks, due to the easier penetration of the developer and to the freeing of grains from the protective effect of the surrounding gelatin. Mild pressure which leaves the emulsion surface undisturbed will, if effected before exposure, desensitize the underlying grains. This effect cannot occur after exposure, so that post-exposure pressure will almost invariably result in a plus-density mark.

Marks of the type described are inseparable from the image and consequently cannot be selectively removed by after-treatment. Mild abrasion marks produced on a processed negative, i.e. simple surface scratches, may often be removed by careful rubbing with cotton wool soaked in methylated spirit. Such marks may often be avoided in the final print by the use of diffuse illumination in enlarging.

Alternatively the negative surface may be treated with a fluid which has a similar refractive index to that of gelatin, so that in effect the scratches are filled in and are not visible on projection. D.Br.

See also: *Faults.*

ABSOLUTE. Term used in special cases in chemistry to denote a pure product, e.g., absolute alcohol.

ABSOLUTE TEMPERATURE. Temperature measured from the Absolute Zero, i.e., the temperature at which virtually all molecular movement ceases (−273° C. or −459° F.). The degrees of the Absolute scale are spaced the same as Centigrade degrees; to turn the latter into °Absolute, add 273. Their only significance to photographers is that all colour temperatures are expressed in terms of degrees on the Absolute scale (also known as the Kelvin scale).

See also: *Colour temperature.*

ABSORPTION. All surfaces absorb some of the light that falls on them. Some, like lampblack, absorb almost all the light; others like white paper, absorb very little. The light energy absorbed is usually converted into heat, but it may be transformed into light of another colour and sent out again or it may produce a chemical change, as in a photographic emulsion.

Colour is the result of selective absorption of light rays of certain wavelengths. If white light falls on a surface that absorbs the red and green rays, the surface appears blue to the eye because that is the only visible light reflected by the surface.

ABSORPTION CURVE. Graphic representation of proportion of light absorbed by a medium, plotted against the wavelength of the light. Generally used to give a scientific indication of the characteristics of colour filters and dyes in colour films.

See also: *Filters.*

ABSTRACT PHOTOGRAPHY

The camera is basically very like the eye. It records the relations of light and shade and draws the relative positions and sizes of various parts of the subject in scientifically correct perspective. So long as the whole photographic process is carried out correctly it gives what is generally accepted to be a true transcription of the scene as it appeared from a given viewpoint. The results are entirely realistic.

This objective realism is very different from the subjective versions of the world produced by the painters, many of whom nowadays hardly ever work direct from nature, but draw their images from impressions absorbed, stored and synthesized in the mind. They commonly express themselves in distorted representations of real things, or even in completely unrecognizable abstract forms.

In the hands of an artist, the camera too, can be made to produce either representational or abstract pictures of aesthetic worth.

There is no rigid dividing line between the two types; whether the picture appears to be representational or abstract will, in some cases, depend on the viewer. Thus specialized photographs made by the scientist may appear entirely abstract when seen by the layman to whom the subject is unfamiliar.

A photograph, though intended to be purely representational, may nevertheless have a strong abstract element in it. This is especially

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

noticeable when an object, possibly of unusual form and texture, is photographed from an unfamiliar angle, or so close up that it can hardly be recognized, or in strange lighting conditions, or with a lack of local colour, or by the use of some special technique, such as infra-red.

Early Examples. Many techniques known in early days produced straight photographs with marked abstract qualities. Geological photographs, for example, revealed the abstract beauty of rock formations and strata. This form of abstraction was used from about 1930 with great effect by Edward Weston in his pictures of rocks, sand dunes and close-ups of pebbles and tree forms. Fifteen years earlier, Paul Strand had revealed the beauty of abstract forms.

Studies of motion produced another peculiarly photographic form of abstraction. As early as 1881 Eakins, Muybridge's collaborator, took superimposed action shots which foreshadowed the multiple electronic flash pictures taken later by Professor Edgerton of such subjects as a golf swing and a drop of milk splashing into a bowl. Many photographs of this type, though made for purely scientific purposes, possess fascinating aesthetic qualities.

The first who deliberately made purely abstract photographs was Alvin Langdon Coburn. In 1917 he made abstracts by taking small objects as seen in the middle of three mirrors, clamped together as in a kaleidoscope: he called them vortographs.

In 1918 Christian Schad made schadographs by placing flat objects and cut-outs on the sensitive emulsion and then exposing it to light. These pictures resembled the cubist collages of the period. This and similar methods of producing images without the use of a camera, developed in 1922 by Man Ray, Moholy-Nagy and others, are known as rayographs and photograms. Man Ray and Moholy Nagy were pioneers also in more strictly photographic methods of making abstracts, such as the use of negative prints, multiple exposures on either plate or paper, and the process known as solarization.

Recent Examples. There has been a considerable development of abstract photography since the war. This is probably a result of the increased acceptance of the more abstract forms of painting, for photographers are very prone to emulate contemporary trends in older arts.

Methods. Among the special techniques that create abstract images of rare beauty are many that can only be applied by scientists with laboratory equipment. While these are taken primarily for scientific reasons, pictures made by such methods have often been included in books of photographic art and are accepted at some advanced exhibitions.

Among these scientific techniques are: X-ray photography, X-ray diffraction photography, the use of the principle of diffraction to photograph air-waves made by a bullet, variations in temperature round a heated object, the stress in a rod, etc., photomicrography, the Lichtenberg figure made directly on film by an electric discharge in gas, astronomical photography, electron micography, high-speed electronic flash, and time-motion studies in which the movements of a worker are recorded by attaching lights to appropriate parts of the body.

But abstract photographs may be made by less ingenious means, without involved specialized techniques and equipment. For many of them only the simplest of cameras is necessary. But the photographer must possess an experimental turn of mind, aesthetic sensibility and imagination.

A camera with focusing screen and with ample extension is almost an essential for some abstraction techniques. It encourages the beginner to study the photographic image on the screen rather than the object being photographed. The camera should, however, be mobile so that the subject may be tackled from any promising angle. A fixed lens reflex camera is excellent in many ways, but has obvious limitations. Most of these are overcome by the single lens reflex camera, which takes fully interchangeable lenses. Other roll film and miniature cameras can of course be used, but as the optical finder does not give the typically photographic image, this has to be visualized in the imagination. The small size may be a drawback in cases where it is planned to apply special after-technique—e.g., solarization.

Generally the urge to abstraction starts with the desire to imitate the rather obvious type of pattern picture that appears nowadays in all the salons—photographs that pick out in close-up or semi-close-up clearly marked lines of rounded kerb, or intersecting curves of plates or other staged still-life objects. These subjects may be treated in a realistic way with full tonal range or may be in high-key.

Both the simplification of subject matter (primary control) and the modification of tones (secondary control) are forms of abstraction which, carried further, can produce surprising and fascinating results. These provide the beginnings of the technique for abstraction.

Primary Controls. Among the effects to be studied are scale, viewpoint, sharpness, perspective, and lighting.

Scale—i.e., the size in relation to the frame—should be studied to observe how the subject's importance is increased by coming closer; how detail can be stressed, how the perspective becomes more violent until the shape of the object is lost and only local surface features remain in almost unrecognizable form.

The viewpoint or angle of approach also changes the appearance of the subject: both in perspective and in the distribution of light and dark masses. A low viewpoint will seem to increase height and importance and looking down may produce a striking, unusual pattern.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Sharpness, blur and combinations of both may be created by suitably focusing the lens. Parts of the subject may be shown bitingly sharp, while more distant ones are left nebulous. This effect is common in extreme close-ups seen through a fairly large aperture and applied to small objects—e.g., fragments of broken glass or glittering Christmas tree decorations—produces fascinating evocative images. Extreme all-over sharpness, especially in very close-up shots concentrating on the surface pattern and texture of such subjects as wood grain, rock erosion and crumbling plaster, can also give many strange abstractions.

Perspective and proportion as controlled by the use of camera movements and optical devices can give further twists to the subject—e.g., by using (or misusing) the tilting of back or front, or both; changing the shapes of things by taking them as reflections in a distorting mirror or bent metal glazing plate; or through a distorting filter of wobbly glass, or through a crude, uncorrected lens.

Lighting effects also play their part in transforming the subject or in stressing certain aspects of it. Surface undulations can be emphasized by oblique side lighting, form can be simplified by strong contrasts in light and shade, or by depriving a part of the subject of light altogether and reducing it to a silhouette.

In dealing with small objects a good method is to use a "light box"—i.e., a box sealed except for holes through which spotlights can be directed and an opening for the camera lens. A variety of objects can be placed inside or suspended. In this way the subject and its shadows cast on to the walls can be made to form abstract patterns.

Out of doors lighting effects can be modified only by varying the direction of approach or waiting for the sun to move, but subjects can be found in unlimited number by looking at things through the camera from all sorts of angles. Any material can be used once the necessary photographic imagination has been cultivated.

Secondary Controls. In addition to the effects that can be directly seen on the focusing screen, the experienced abstract photographer can look at the image and visualize how he can change it in the final print by one or more of a number of after-processes—e.g., after it has been enormously enlarged, modified by a filter, or photographed on an infra-red emulsion. If the subject is moving or has moving parts, he will try to visualize it as wholly or partly blurred. He may even visualize it with another image superimposed on it.

The following are some of the methods that may be used. Many of them are processes of simplification. The aim may be to cut out half-tones and reduce the image to a simple statement in black and white, or to eliminate local colour in order to stress form, or to modify the colour rendering so as to set off one part of the subject against another.

Exposure and development are the first and most obvious controls. Over-exposure with full development applied to a flatly-lighted subject can give an interesting effect: printed on a contrast paper the lighter tones will be almost invisible, but the edges of objects and other darker areas will stand out boldly. The effect can be made stronger by applying Farmer's reducer to the negative. Under-exposure is useful for simplifying shadows and stressing the planes and ups and downs of the subject. If in addition the negative is greatly over-developed, there will be very fierce contrasts of black and white, especially if there was also contrasty lighting.

In flatly-lighted subjects contrast can be obtained by the use of blue-sensitive or special contrast emulsions, combined if necessary with prolonged development. This technique is useful for stressing local detail and texture; such things as the grain in wood or the surface texture of stone. Local colour patterns can be emphasized in various ways by the many filters available. Infra-red plates give great scope for creating weirdly unreal landscapes, and pictures of plant forms. They can also give surprising results when applied to other subjects: the results are not always predictable, but experiments are well worth while.

The negative can be modified either during or after development. Solarization is one of the most promising ways of making radical changes in the normal negative image. The process is, however, somewhat uncertain and it is always advisable not to use a valuable negative, but to experiment with duplicates. Enlargements of solarized negatives have a peculiar beauty of their own, abrupt contrasts are absent and contours appear as if outlined with a light crayon. Solarization gives the best effects with subjects having strong contrast and good outlines. The method can be applied equally well to positive transparencies, when the outline will print black.

The abstract qualities of the negative itself may be exploited by making a positive transparency from it to give a negative instead of a positive print. Or by placing negative and positive in contact, slightly out of register, and printing them together on a contrasty paper, the contours of the subject will be outlined in black or white. By altering the position of the positive on the negative, the width of line may be varied, and by varying the degree of hardness of the plates and printing paper, the print may be made in either strong black and white or grey tones.

Greatly enlarging a coarse-grained negative, or better still, deliberately inducing reticulation may destroy fine details and local textural qualities, thus simplifying the image and giving it a monumental quality. Grain and textural effects can also be introduced by printing through a texture screen, but the method of using a grainy negative or positive is more

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

interesting, because the graininess forms an organic part of the image. A granulated negative will give a white network in the print, the positive a black one. Further effects may be created by combining negative and positive, one or both granulated.

Another technique that has been occasionally used with effect consists of distorting the image by heating a wet negative until the gelatin just melts and begins to run. The whole or part of the negative may be dipped in hot water, or heat may be applied locally by other means.

In enlarging, the negative or the paper, or both, can be tilted and the picture can be elongated or compressed. Or the paper can be curved or distorted in various ways. Opaque and semi-transparent masks suitably shaped make it possible to hold back or change the definition of certain parts.

Multiple Images. In addition to superimposing negative and positive versions of the same image, entirely different images can be combined in negative or positive form or both. They can be either enlarged together, or one printed and developed first, the print rinsed, but not fixed, and replaced on the enlarger for a further exposure from another negative. For further control, parts of the images may be held back in the printing or wholly or partially bleached away.

Superimposition can, of course, also be done direct in the camera, and every photographer will know that even accidental double exposures can sometimes be very attractive. When they are planned, an effort should be made to memorize the arrangement of masses in the first picture so that the second image falls in the best place to achieve the desired contrasts, balance and rhythm. Subjects with large, simple masses of shadow generally give the best results. Interesting effects may also be created by making multiple exposures on the same subject, and slightly moving—or better still, revolving—the camera between each exposure.

Odd combinations and strange contrasts can be obtained also by photo-montage done on a fairly large scale and then copying the mounted composite print. This method, however, unless done very skilfully, tends to look unconvincing and rather unphotographic, because the blending of the images is not really organic.

The recording by the camera of movement, moving objects and lights, has been extensively exploited for obtaining abstract images, either as blurs or clearly-defined patterns. And multiple exposures of arrested movement have also produced interesting abstractions. Complex linear patterns have been made in large number by recording the diminishing travel of a small light attached to a pendulum. Often referred to as physiographs, the idea can be further elaborated by using several lights fixed to a whole system of pendulums, or by making overlapping patterns by means of multiple exposures. Interesting linear effects can be created in other ways—e.g., by recording the lights of moving traffic. H.v.W. & R.May.

Books: *All the Photo Tricks*, by Edwin Smith (London); *The Complete Art of Printing and Enlarging* and *Design by Photography*, both by O. R. Croy (London).

ACCELERATOR. Another name for the alkali in a developer. That constituent of a developer which increases its speed of action.

ACCESSORY SHOE. Metal shoe fitted to the top of the camera to allow supplementary items such as a rangefinder, a flash unit, or a viewfinder to be fixed to it. Most manufacturers of cameras and accessories follow the dimensions adopted by the leading Continental miniature cameras, but some in the past have not, so the point should be checked when buying an accessory for this type of fitting.

Some cameras have an insulated flash synchronising contact built into the accessory shoe. This automatically connects to a corresponding contact in the base of the maker's own flash attachment and there is no need for an external plug-in synchronising lead.

ACCIDENTS. Photographs of road accidents may be taken for their news value or for use as evidence in a court of law. For the latter, special requirements may exist.

See also: *Evidence by photographs; Traffic photography.*

ACCUMULATOR. Secondary electric storage cell which produces a current after being charged from an outside current supply. When the current stored in an accumulator is used up, it can be recharged. The best known type is the lead acid accumulator.

See also: *Batteries.*

ACETATE FILM. Also tri-acetate film. So-called safety film. The term refers to the base of the film which consists of cellulose acetate instead of the inflammable nitrate, which it has almost completely replaced in all film types.

See also: *Supports for emulsions.*

ACETIC ACID. Chemical used as acid in stop baths, acid hardening fixers and certain bleachers and toners.

Formula and molecular weight: CH_3COOH; 60.

Characteristics: Colourless, corrosive liquid with strong irritating smell of vinegar. The pure acid (glacial acetic acid) solidifies below 62° F. (16·5° C.).

Solubility: Mixes with water in all proportions.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

ACETONE. Dimethyl ketone. Solvent in certain processing solutions which contain substances not easily soluble in water. Also solvent in film cements, preparations for varnishing negatives, etc.

Formula and molecular weight: $(CH_3)_2CO$; 58.

Characteristics: Colourless, pleasant smelling liquid. Highly inflammable.

Solubility: Mixes with water in all proportions.

ACHROMATIC. Term applied to a lens which has been corrected for chromatic aberration so that it brings light rays of two colours in the visible spectrum to the same focus.

The term is also used in colour physics to describe colours which have no hue or saturation and possess only lightness. Thus white, greys and black are examples of achromatic colours.

See also: *Aberration of lenses; Colour measurement.*

ACID. Hydrogen compound in which the hydrogen can be replaced by a metal (or by a group of molecules with similar characteristics) to form a compound known as a salt, e.g., the metal sodium will replace the hydrogen atom in hydrochloric acid to form the salt, sodium chloride.

The strengths of the various acids are compared on the basis of the pH values which depend both on the characteristics of the acid and on its concentration. Strong acids are generally corrosive. Dilute acids have a sharp taste and most will turn blue litmus red. Any solution with a pH value below 7 is acidic.

See also: *Indicator chemicals*

ACID FIXER. Fixing bath for negatives or prints which contains an acid component in addition to the fixing agent, sodium thiosulphate (hypo).

The acid neutralizes the developer carried over on the sensitized material and stops its action. This prevents prints from going darker in the fixing bath and lessens the risk of staining and uneven development when a number of prints are in contact in the bath.

ACID RINSE. Another name for stop bath used to stop development before transferring material to the fixer.

ACRES, BIRT. Dates unknown. British photographer and manufacturer. Pioneer of cinematography and of the film industry who obtained, independently of his French contemporaries, patents on a chronophotograph (1893) and a cinematograph (1895). Collaborated with R. W. Paul. Also designed the first narrow gauge (half of 35 mm.) camera (Birtac) and made, in 1895, the first British film.

ACTINIC. Term referring to the ability of light to change the nature of materials exposed to it. The rays at the blue-violet end of the spectrum are generally regarded as being the more highly actinic, since it is these rays that most strongly affect the photographic emulsion, can cause chemical action, and also cause sunburn.

ACTINOMETER. From the mid-1850s there were exposure meters, e.g. Louis Bing's (1866) and Walter Woodbury's (1879). In these meters a piece of sensitized paper was exposed to the light until it darkened to a standard tint. The number of second or minutes it took to reach this tint was measured by stop watch, and a calculator converted this time into the correct exposure for any type of sensitive material.

If the sensitive surface were held at an angle to the main lighting the exposure would be incorrect. Actinometers were apt to give unreliable readings in hazy or cloudy weather. At such times, because there is then no major source of light, the general level of illumination is lower, and shadows where they exist are much lighter than they are in clear sunshine. Hence actinometers were liable to give overexposed negatives when the weather was cloudy.

By choosing a suitable stop, the photographer could use this type of meter to give him the length of the actual exposure. He simply opened the camera shutter and exposed the sensitized paper at the same time; when the paper darkened to the standard tint, he closed the shutter again.

Meters of this sort were usually about the size and shape of a pocket watch. The sensitized paper was supplied as circular discs which were loaded into the back of the instrument. Small areas of the paper could be exposed in succession through a hole in the dial. A standard tint printed next to the hole told the user when the paper had darkened to the right degree. The face of the dial carried the necessary calculator for converting "time to darken" into "exposure." These meters were very suitable for the slow sensitive materials of the earlier days, but are now inconveniently slow.

The modern integrating meters proper are large instruments which not only measure the amount of light necessary for the correct exposure of the negative, but operate a shutter, switch off lamps, or do anything else that may be required at the end of the exposure. They usually have a vacuum-type photo-electric cell, the output of which is amplified by a valve amplifier and used to operate a counter geared to count exposure units. A clock is pre-set to the required number of exposure units and as the exposure units are received by the instrument, a hand travels across the face of the

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

resistance, is very susceptible to mould and microbiological attack. K.S.M.

Optical Cements. Optical cements are usually classified as either thermo-setting or thermo-plastic materials. Canada balsam, which has been used for two centuries or longer, is still widely employed. It is representative of the thermo-plastic group. For many optical requirements, however, other substances must take its place. This is especially the case when considerations of resistance to high and low temperatures, moisture-proof qualities, and excellent adhesion are very important. The more modern cements which have these improved properties include cellulose caprate, n-butyl methacrylate, polyester resins, vinyl acetate, and certain formulations based on epoxy resins. In general these new types are thermo-setting since they become rigid on heating; the chemical process involved is known as polymerization. Cellulose caprate is a notable exception for it is a solid which softens in the region 95–100°C. If the final cement is too brittle it may be improved by the addition of a plasticizer which is either a high-boiling liquid or a low-melting solid.

When using optical cements it is important to ensure the utmost care in preserving a clean material. This is especially so if the cemented film appears in the focal plane of the instrument as with graticules and the field lenses of binoculars. Light transmission of a high order and an appropriate refractive index are other valuable features of a satisfactory optical cement.

In cementing lenses it is usual first to apply the material to the glass surfaces as a viscous liquid taking care to avoid the introduction of air bubbles. Further treatment varies according to the type of cement. For a cold-setting formulation, say, of a polyester resin, the cemented units are allowed to remain in a suitable jig until the polymerization process is complete. Some cements require heat treatment either to remove a solvent as for Canada balsam or to complete the polymerization process as with n-butyl methacrylate. The temperature of baking may be in the range 40°C. to 100°C. and the time from a few hours to as many days, the conditions selected being determined by a number of factors including the nature of the cement, the degree of permissible strain in the joint and subsequent likely exposure to thermal and mechanical shock. E.Bo.

See also: *Adhesive tape.*

ADHESIVE TAPE. Many of the wide variety of types of self-adhesive tape are used in photography in place of other agents like gum, glue, drawing pins and so on. Here are the principal types with photographic applications.

Transparent Cellulose Tape. This is the popular sticky tape used for repairing torn papers, books and photographs. It makes a quick, foolproof fastener for anchoring the end of bulk film to the film spool or for rejoining a cut length of roll film to the paper backing. It can be used to protect bottle labels from contact with water and dark room chemicals and it will hold papers flat for copying.

P.V.C. Tape. This is a tough, flexible, waterproof tape used for electrical insulation, for putting a waterproof seal around film containers, for temporary repairs to processing dishes and tanks, camera bellows and so on.

Cloth-based Plasticized Tape. This is a thicker and stronger type of self-adhesive tape which is suitable for book and album binding, for repairing camera cases and hold-alls and for covering polished and plated parts, e.g. control knobs, levers and handles, to make them easier to grip.

Double-sided Tape. This is a tape that is sticky on both sides. When bought in a roll, one side is covered with a protective layer of paper which is stripped off before use. Double-sided tape can be used for holding the printing paper down on the enlarging easel and is specially useful for big enlargements that have to be stuck to a vertical wall surface. It is also used for holding printed material for copying.

Light-reflecting Tape. Various kinds of light-reflecting tape—UV-sensitive, fluorescent, glass-beaded and metallized tape are used in commercial and industrial darkrooms where panchromatic materials are manufactured or processed by very dim safelight.

Splicing Tapes. Self-adhesive cine film splicing tape is made up in lengths equal to 4 frames of film with a peel-off protective paper over the sticky side. Self-adhesive tape for splicing magnetic recording tape is supplied in rolls and is coated with a specially hard adhesive. In this case, the splicing tape is applied only to the back—i.e. the shiny side—of the tape because nothing must come between the magnetic coating and the face of the recording head.

See also: *Adhesive; Splicing.*

AERIAL FOG. Type of chemical fog affecting negative materials if they are excessively exposed to air when wet with developer.

See also: *Faults; Fogging.*

AERIAL PERSPECTIVE. General effect of depth created by haze in a photograph of a landscape. There is usually a certain amount of haze—water vapour, smoke, or dust—in the air and the amount between the lens and the subject increases with the distance of the subject. So distant objects have softer outlines and lighter tones than those closer to the camera. The eye accepts this increase of haziness with distance as an indication of depth and spaciousness. Haziness can be controlled by using a yellow, orange, or red filter with a panchromatic film or plate. In telephotography of distant views where aerial fog is a drawback it can often be cut out altogether by using an infra-red film or plate and filter in combination.

CC-0. Agamnigam Digital Preservation Foundation of Chandigarh

AERIAL PHOTOGRAPHY. Photography of terrain on the ground and objects in the air from cameras mounted in aircraft. Civilian and military applications range from aerial survey to reconnaissance, strike recording, missile tracking and satellite photography.

Air-to-ground photography comprises all pictures taken of features on the ground from aircraft. The type of camera and technique employed depends on the purpose for which pictures are required. For aerial survey the ground is photographed in a systematic manner to cover the whole of a specified area. This provides the necessary data for map-making and other survey applications. Reconnaissance photography, especially in wartime, aims at recording individual ground features.

Air-to-air photography may include the recording of other aircraft in flight, but the widest field of application is the photography (usually with motion picture cameras) of bullets and missiles aimed at target aircraft. The recording cameras may either be mounted alongside the guns, or in the target aircraft itself to record strikes by guided or automatic missiles. Different types of equipment are required for these two applications.

Ground-to-air photography is concerned with tracking flying objects, from missiles to satellites, during flight. Cameras for this purpose are usually very large and have long focus lenses and complicated movable mountings to track a flying object.

See also: *Aerial survey; Aircraft camera; Air Force photography; Air photographs; Air-to-air photography.*

AERIAL SURVEY

Photographic recording of the topography of the ground by airborne cameras. The value of photographic surveys made from the air was realized as early as 1858 when, on 23rd October, Nadar took out a French patent for "an entirely new system of photography, whereby photographic bird's-eye views of portions of the earth's surface may be taken". The camera was fixed either vertically in the bottom of the balloon car or in the side of the car for angle shots. After many failures, Nadar succeeded in obtaining a distinct, though faint, image from about 80 metres above the village of Petite-Bicêtre near Paris in winter 1858. In the 1860s. Nadar took some good views of Paris from a captive balloon from heights of up to 500 metres, but balloon photography with collodion wet plates was not reliable enough ever to carry out his plan that the whole of France should be photographed from the air for the purpose of ordnance survey. A United States patent was taken out to cover the making of maps from a balloon in 1873. Since that time the techniques have been extensively developed, and today complete national surveys are made by air, e.g. Great Britain and Canada.

In general, aerial survey falls into two categories: qualitative or quantitative, and photogrammetric. The first is mainly concerned with size, shape, tone and texture, some overall distortion being acceptable in many cases: its applications lie in agriculture, archaeology, military reconnaissance, etc. In photogrammetric survey, position and direction, and therefore undistorted reproduction, is usually the most important factor. This type is used in map making and it accounts for the majority of aerial photographic effort in peacetime. Both categories demand the best possible definition. Both also involve three phases: planning; photography; and interpretation or analysis..

Equipment and Materials. In contrast to military reconnaissance, cost is a major factor in commercial survey. While the use of long-focus lenses from great heights may seem preferable, costs as well as atmospheric conditions usually dictate otherwise. By covering more ground from lower altitudes, wide-angle lenses entail among other things lower fuel consumption, less mileage flown and less film used. There is also the important advantage of having larger areas of overlap for stereoscopy, with greater distances between viewpoints, giving exaggerated and more measurable perspective displacement. The distortion and errors involved can be more economically corrected in specialized printing and analyzing equipment. Since accuracy is generally more important than time, slower, more suitable and more economical aircraft can be used, often with relatively simple equipment.

The type of work determines the size and complexity of equipment used. It ranges from light, fast-operating hand-held cameras using film up to about 5½ ins. wide, to large, automatic, remote-controlled fixed instruments taking up to 18-ins. wide film or even plates. All are characterized by fast recycling operation, highly corrected lenses, usually interchangeable, and special precautions to ensure film flatness. In many, the latter is achieved by pressing the film against a register glass which may be engraved with a grid or fiducial marks to assist measurement; in others, the film is flattened by suction against a back platen.

Shutters may be of the focal plane type but inter-lens shutters are preferable since they introduce no distortion. These have to be large and may be electrically or spring driven, giving exposures up to about 1/1,000 second. Fast shutter speeds to overcome blurring due to the aircraft's movement involve wide-aperture lenses and fast film. An alternative is Image Motion Compensation (IMC), in which the film is moved during exposure in step with the image movement, either by moving the platen

AGAINST THE LIGHT

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The very expression "against the light" (or "contre-jour") implies something out of the way and difficult. This is a pity as it makes many photographers keep to the safe rule of having the light source behind the camera when they could get more attractive pictures with the light source in front. There is nothing particularly difficult about the technique: the main necessity is to keep sunlight or direct light from any other source from reaching the lens, where it would cause fog and flare on the film.

There are many good reasons for taking pictures against the light. One is to deal with messy and fussy backgrounds or even ugly plain ones—e.g., brick walls. Against the light shots show less detail in any case, and the background is likely to be in the shade and therefore under-exposed and dark.

It is the unusual patterns of light and shade that make the majority of against the light photographs. By careful positioning it is possible to include all the principal shadows cast by the subject in the picture frame. The best effects are produced in the morning and evening, when the shadows are long. And if the camera looks down from a high viewpoint the effect is even better as the shadows will not be foreshortened. Long shadows have another valuable effect apart from forming interesting patterns: by projecting towards the camera they give the picture more depth and three-dimensional reality than can be achieved by other normal means.

DIRECTION OF THE LIGHT. The sun directly behind the subject casts the shadow straight towards the camera. Both edges of the object may be outlined with a bright light rim. When the sun comes slightly from one side, the shadow is cast in the opposite direction and only one side is rim-lit.

The sun also produces a bright rim of light round the edges of objects and this rim-lighting is a further effect that helps to make the subject stand out from its background. In addition, the rim of light makes the subject appear attractively luminous. This luminosity is the greatest charm of against-the-light pictures. It can be increased still more by using a soft focus lens or fitting a diffusing disc before the camera lens. When the image is diffused in this way, the luminosity pervades even the shadow areas.

Shielding the Lens. A really efficient lens hood is always advisable but against the light it becomes an absolute necessity. When lens hoods leave the factory they are usually dull black inside, but if after long use or by accident they become bright inside they must be given a coat of dead black paint or they will cause the very trouble they are intended to prevent.

The lens hood should be as long and narrow as possible without cutting off the corners of the negative; the safest policy is to buy the one made for the particular camera and lens.

When shooting so much into the sun that even the lens hood cannot shade the lens completely, it is often possible to get over the difficulty by choosing a camera position in the shade of a doorway, building, tree, or even a telegraph pole, or a friend can hold a hat or wallet to shield the camera if there is no natural shade. Of course, he must take care not to intrude into the field of view. If the camera is on a tripod, there is no difficulty in shielding the lens in this way with the free hand, and even without a tripod it is still possible to hold the camera with one hand at shutter speeds of 1/100 second or shorter.

Suitable Subjects. People, boats, and in fact most snapshot subjects and all pictures of activity come out well against the light. Pictures of snow and most subjects that owe their appeal to texture or sparkle are always improved by being taken against the light. With foliage, flowers, icicles and anything thin enough to let the light shine through, there is a striking translucent effect which is most attractive. Sun shining on steam or mist can be successfully exploited in against the light shots.

Landscape photographs when normally lighted are often difficult because they so frequently suffer from a lack of tone contrast. Against the light, they come to life because the shadows separate the receding planes and give them depth and atmosphere. This technique cannot be used if detail must appear in the far distance because everything near the horizon tends to disappear in haze.

When the sun hides behind clouds or shows through a thin cloud or through mist it can safely be included in the picture. Even the dullest landscape can be made into a successful

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

HEIGHT OF THE SUN. The higher the sun, the shorter the shadow of the subject. Low sun provides the best lighting for against-the-light subjects, as it creates more pictorial shadow pattern and the shadows tend to be mellower.

picture by putting the horizon to the bottom of the picture and making the sky the main theme with the sun painting dazzling rims round the clouds. This technique is particularly effective with sunsets.

Artificial light sources—e.g., street lamps—can often be usefully included in the picture by taking the photograph at dusk when the sky is still quite light but not bright enough to cancel them out. After dark, weak and diffused lamps can still be included but the camera should be kept at least thirty feet away from them. Strong lights, like motor car headlamps, must not shine straight into the lens but can be photographed if the actual bulb is shaded by its own reflector—i.e., if the picture is taken from the side. Street scenes at night are vastly improved when the pavement is wet because then the picture is enriched with reflections of the light sources.

Sunbeams shining through windows into a room make fine pictures and it can be worth while to shake a mat or rug to raise some extra dust to give the beams more brilliance.

Balancing Contrast. When taking close-ups against the light there may be too much contrast between light and shadow areas for the film to cope with both extremes. In such cases it is an advantage if the shadows can be brightened by the use of a reflector or fill-in flash. Out of doors, the greatest contrast exists when the sun shines from a cloudless sky; it is always much reduced by reflections from white clouds and still more by any light haze or mist. Light-coloured surroundings such as a sandy beach or snow reflect so much light into the shadows that they provide the ideal location for against the light portraits or animal close-ups. When there is no natural reflection it may be possible to place the subject near a light coloured wall, or to use an artificial reflector—e.g., a piece of white or light mounting board or even a newspaper.

Flash can also be employed to lighten the shadows and has the advantage of being much more flexible and independent of the other prevailing light. The flash can be mounted on the camera, and either flash bulbs or electronic units are suitable.

With fill-in flash, the exposure for the daylight and for the flash must be balanced to avoid overlighting the shadows and so destroying the natural against-the-light effect. The best way of ensuring this is to keep the lighting level from the flash at about one-quarter the light intensity from the daylight. In other words, the flash-lit shadow areas should receive about one-quarter the exposure they would need for full illumination.

A handy method of doing that is to work out the daylight exposure by pointing the exposure meter with incident light attachment at the light source, and ascertaining the aperture at a shutter speed at which the flash can be synchronized (with bulbs and simple cameras this would probably be 1/30 second). This aperture is then divided into double the guide number normally used for the flash, and the result used as the flash distance for the fill-in lighting. If this is different from the camera distance, the flash may be used off the camera (with an extension flash cable) to bring it nearer to or further away from the shadow areas. Alternatively, if the flash is too strong, it may be possible to reduce the light by one or more thicknesses of a normal handkerchief in front of the flash reflector.

Exposure. The exposure depends on the type of picture aimed at. This applies particularly when the sky is used as a background and there is no possibility of illuminating the foreground (or the subject in a close-up). If these parts of the picture must show detail there is nothing for it but to over-expose the sky. A great improvement can be effected by renouncing the close-up—which always demands extra exposure anyway—and taking the picture from a greater distance. By finding the half-way exposure between highlights and shadows it is then possible to get detail in both. If it is not possible to take the picture from a greater distance there remains the possibility, especially when the background is a fine cloudscape, of making the foreground object into a silhouette by exposing for the clouds.

Open landscapes taken against the light need a fairly short exposure. But the strong and dazzling reflections of sun on water are apt to

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

mislead the photographer into giving too short an exposure. If the exposure is based on these highlights the result will be a picture with a night effect.

Sensitized Material. The fastest films are the softest and therefore best able to manage the greater contrasts of against the light photographs. Similarly, soft developers help to prevent the highlights from blocking up and becoming impossible to print. With correct exposure on a good film containing all kinds of subjects there is no need to alter normal development technique, but there must never be any tendency towards over-development. It may be necessary to print on a softer grade of bromide paper, and luminous against the light shots often print better on soft paper.

Colour Shots Against the Light. A colour transparency can reproduce particularly effectively the great brightness range of against-the-light scenes and still preserve the luminosity of the shadows. The transparency can thus give an enhanced impression of depth when a darkish foreground object is lit from behind against the bright background.

Since colour films have a limited exposure latitude, the exposure for against-the-light shots is particularly critical. Generally it is impossible to avoid some colour distortion in the darker parts. Exposures with transparency film should however be based on the highlights, since colour errors there are most noticeable. Only extremely bright catch lights and haloes of light are acceptable overexposed. Generally the exposure should be based on a highlight reading with an exposure meter of the brightest subject area that must show detail.

Alternatively a reading with an incident light meter pointing in a direction halfway between the sun and the camera gives a reasonably good result.

For effective results in colour it is advisable to lighten up the shadows by suitable fill-in lighting. Reflecting areas here need special care, since any coloured reflector is apt to give the subject a cast in the colour of the reflecting surface.

Fill-in flash is ideal here, using blue-tinted flash bulbs or electronic flash. The exposure is worked out in much the same way as when using fill-in flash for black and white shots, but the lighting ratio should be 1 : 3, rather than 1 : 4. So after working out the flash to subject distance in a manner already described, reduce this distance by one-fifth.

Against-the-light shots are rarely successful on negative colour film, because neither the film nor the paper print can satisfactorily deal with the extreme contrasts involved. Fill-in lighting there becomes indispensable. The lighting ratio between the flash and the daylight should be higher still—around 1 : 2. In practice this can be allowed for by assuming for fill-in purposes a guide number 50 per cent higher than the normal guide number of the flash.

H.W.

AGEING OF MATERIALS. Sensitized materials that are stored for long periods gradually lose their sensitivity, and may also change other characteristics. Troubles such as fogging and mottle can also arise. The extent to which these effects occur depends a great deal on the conditions of storage.

AGENCIES. Almost invariably, the photographer who has produced a saleable picture or picture sequence stands to gain most by letting an agency market his work for him. Taking saleable pictures and selling them require two entirely different kinds of experience.

The agent is in constant communication with editors and others who buy photographs, so he is highly informed about current market requirements and can place saleable work before the most likely buyer with minimum delay and maximum economy. The agent is also well informed about the relative prices paid for mediocre, good or excellent pictures in various markets, so he knows what a particular photograph is worth and how much to ask for it.

In return for his services the agent takes a commission on sales.

News Agencies. A news agency is a big organization. It employs a staff of photographers who cover the main daily news events, and their pictures are circulated to a large number of journals.

The news agency also accepts work on a percentage basis from free-lances or amateurs who happen to be on the scene when something of news value occurs.

The usual procedure for a free-lance who has a live news picture that he wants to place through an agent is first to telephone the agency, explain the happening and state what pictures were obtained. Then if the agency is close at hand, he should take or send the undeveloped film to the agency. If he is in another town, he should pack the film, clearly marked "Press matter. Urgent. To be called for", and address it with the agency's name and the terminus station and send it by rail or, where appropriate, by air.

Inside the pack, he should enclose a note marked "Undeveloped film". In addition, he must include caption material based on the six imperatives of news reporting: who, what, why, when, where and how? Many a first-class picture fails to get published through lack of full information.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The film will be processed by the agency and prints made and circulated (often within half an hour of getting the film) to a number of news editors on a non-exclusive basis. (Top-line agencies now have branches with wire machines in all large towns.) No photographer working alone could hope to do this. The news agency service often covers foreign markets, too, and it is not unusual for a single news picture of merit to be sold fifty times.

The news agency will take 50 or 60 per cent of sales revenue. This is a fair return in view of the printing costs, staff hours and the highly organized distribution that makes so many sales possible.

Feature Agencies. The feature agency deals with pictures of general interest which are neither as topical nor as urgent as those handled by a news agency. A feature picture deals with a particular aspect of the news—e.g., photographs of a race meeting are news pictures, whereas photographs of the faces of the spectators, showing their various reactions, are feature pictures. The best feature agencies probably supply editors with the greater part of the pictures they use on personalities, beauty, interesting occurrences, ways of doing things, people with unusual hobbies or queer pets, new developments in the social sciences and amenities, and anything of a curious or humorous nature—in fact, whatever is of general interest, but not direct news.

The free-lance who tries to cover the news interest of an event at which staff photographers are present is often wasting his time. His best plan is to look for a feature that has escaped their notice. Good pictures in this class can be sold days after the event, when straight news pictures are dead.

Feature Agency Terms. The photographer who makes use of the best type of feature agency can expect the following conditions.

The photographer will supply negatives and contact prints. From these, the agency editor will order from his own printer enough single pictures or sets to supply all interested markets at home and abroad. The agent deducts a fixed percentage share. As terms do vary somewhat with different agencies the photographer should get exact terms from his agent in writing.

Advice on sales possibilities of a proposed picture or picture-story will be given before it is undertaken. The agent is always ready to discuss the photographer's ideas for pictures or series and his wider experience often enables him to add just the necessary angle, or twist, that will make a story saleable. There should be no charge for this or any other extra service.

Current information on editorial trends and requirements should be passed on by the agent to the free-lances who deal with him. He should point out in particular when there is a possibility of a suitable feature in the photographer's own district.

Assignments. Commissions are received by some agents from editors, mainly of overseas magazines, who wish to run a story on an event or personality in this country. This well-paid work is handed out by the agents to free-lances, and preference is naturally given to those who bring in original material of their own.

The agent may finance a story of the photographer's choosing, if he feels that the chance of success is worth the risk. This enables the free-lance to undertake a worth-while story which he could not afford to proceed with on his own.

It sometimes takes a month or more for the agent to receive payment from an editor. If the agent feels that a photographer is able to produce regular, saleable work, he may advance him a weekly sum of money until payment for sales catches up.

Pictures can lie in a photographer's files for years without being sold. If they are kept in an agent's files, they will constantly be turned over by book illustrators, calendar printers, advertisers, artists needing a picture for reference, and magazine representatives looking for pictures of a particular subject. Landscapes, happy children, pretty girls, pets and beach scenes, are among the file pictures which may sell five weeks or five years after they were taken.

For National Press, and most other uses, a fee of two guineas upwards is normally paid in the United Kingdom, depending on the purpose for which the picture is required. With the provincial press payment may be lower, around £1 7s. 6d. In certain cases a calendar printer may pay fifteen guineas. Twenty would be quite ordinary for a national magazine cover, and a picture chosen for a national advertising campaign might well fetch more.

There is a ready market for colour material for editorial, advertising, calendar, etc., use and the leading agencies maintain comprehensive libraries of colour photographs of many subjects. Fees paid vary between ten guineas and 100 guineas, and may in special cases even exceed the latter. 35 mm. transparencies are extremely difficult to market in the United Kingdom. The minimum size normally accepted by an agency is 2¼ ins. square, but the standard material for the colour market is 4 × 5 ins. and larger. Only the highest quality colour pictures are generally considered by an agency.

The commission varies from agent to agent. One agent will charge a commission of 50 per cent on home and overseas sales, and pay all of the costs of printing. Another may charge 40 per cent and pay half the printing costs. Probably the lowest commission asked by an agent is 35 per cent on home sales, 50 per cent on overseas sales (which have to be shared with the overseas agent) and a share of the printing cost.

Exclusive Rights. These are the most important words in picture selling and in the agent-

CC-0. Agamnigam Digital Preservation Foundation Chennai

photographer relationship. News agencies normally offer pictures to news editors on a non-exclusive basis. The editor pays a standard rate, and knows that the picture may be bought by his competitors as well. On the other hand, a feature editor will pay five or ten times as much for a feature picture on an exclusive basis, knowing that it will enhance his paper's reputation for original pictures. He will seldom buy a good feature picture offered on a non-exclusive basis, because he knows it may also be used by a competitor.

The good agent obtains the highest fees possible by selling "first publication rights" to a single paper or magazine. The photographer must of course tell his agent if a picture supplied by him has already been sold or he may be responsible for a serious infringement of copyright or exclusive rights as a result of which both parties might have to pay heavily in cash and reputation.

Specialist Agencies. Apart from the general agencies, there are a number of small specialist agencies, each concerned with supplying pictures to a limited market, such as art or technical journals, or those concerned with the theatre, fashion or travel. Each of these is well known to editors, dealers, the trade, and publicity firms concerned with that particular market. These agents know what pictures are in demand in their own spheres and so know exactly where to place free-lance pictures that meet their requirements.

Having found a good agent, the photographer will do well to stay with him. Changing about and sending sets to various agents in order to find out which makes most money, serves no useful purpose. A picture can only be offered by one agent at a time, so direct comparison is not possible.

Buying from an Agency. Anyone requiring a photograph for reproduction or display should telephone an agency that specializes in the particular subject or is likely to have a selection of pictures dealing with it. This is better than making a personal call in the first instance, as it will give the agency's librarian time to look out suitable material in advance. Some agencies charge a search fee for this.

Agencies do not like sending out selections of file copies except to regular clients. The trouble involved in sorting and sending, and the incidental costs of recovering unreturned prints and reprinting damaged ones, is not covered by the fees paid for those sold. R.S.

Books: *How to Take Photographs that Editors will Buy*, by R. Spillman (London).

AGITATION. Term applied to the various methods of keeping the solution or sensitive material in motion during processing. The movement is intended to bring fresh chemicals into contact with the emulsion surface.

The usual method of agitation is to move the film either intermittently or continuously during processing. Daylight processing tanks for single film lengths incorporate a rod which engages with the film bobbin so that it can be rotated; some types also allow vertical agitation by pushing downwards on the rod. A more recent type of daylight tank is designed for agitation by inversion—i.e. the top of the tank is stoppered, and the tank is completely inverted and returned to its right-way-up position at the specified intervals. The older method of agitation by means of a rod is probably the more satisfactory, and cleaner. Plate tanks do not usually have agitators and it is necessary to rock the whole tank body.

Mechanical devices for automatic agitation have been tried, but motor driven agitation is liable to cause uneven processing due to the regular intermittent effect of the power with all but the smoothest motors.

The most widely used current method in colour processing is nitrogen burst agitation. This is suitable only for larger tanks, as used for sheet films, and involves blowing a short intermittent burst of a neutral gas (usually nitrogen) into the developing solution (ordinary air would oxidize the developer too quickly). The gas is derived from cylinders, and burst intensity controlled by a pressure valve. In most cases a timing system opens the valve automatically at pre-determined intervals, to provide a regular and repeatable degree of agitation. This system needs additional equipment (gas supply, valve gear and tubes to lead the nitrogen gas into the tanks) but once installed requires little or no attention. Outfits are available in various sizes, according to the capacity of the tank system.

NITROGEN BURST EQUIPMENT. Gas burst agitation relies on the insertion of a hollow perforated grid-like gas distributor (top) into the developing tank. Usually every tank has such a distributor. These are fed from a gas cylinder via a timing valve which releases bursts of nitrogen gas at pre-set intervals to stir up the liquid.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

Other agitation methods that have been tried include ultrasonic vibrations, produced by a quartz crystal or other generator. These vibrations break up the local concentrations of chemicals formed during the processing reactions and thus provide a uniform degree of mixing throughout the solution, without requiring the bodily movement of large solution quantities.

For highly standardized processing conditions (as specified for the development of film samples tested for speed) continuous agitation is nearly always essential. This may take the form of constant inversion of the vessel containing the developer, or of sweeping it across the surface of the sensitive material mechanically.

Continuous processing machines for roll films or roll papers as well as motion picture films produce the necessary agitation by the constant movement of the sensitive material through the solution. This may be supplemented by other methods such as gas burst agitation. Where films or papers are fixed to drums dipping into the developing solution constant movement is essential to keep the surface of the material wet all the time.

When processing large sheets of material (for example for photo murals) the processing solutions are usually applied by a spray (frequently connected to a recirculating pump system) or by swabbing over the surface. Both correspond to continuous agitation. L.A.M.

AIR BELLS. Bubbles of air which adhere to the surface of the emulsion on plates, films and printing papers. Unless removed by brushing the surface with the finger or by agitating the solution, these bubbles prevent the developer from acting on the emulsion and leave clear spots on the finished negative. The use of a wetting agent does much to stop air bells from forming.

AIR BRUSH

The air brush has been in existence for well over fifty years and during that time has become an essential tool for every commercial art studio. It brings within the scope of the artist effects that are difficult, if not impossible, to obtain with the ordinary brush. Colour can be much more quickly applied than with any type of brush with the added quality of a perfectly even coat and the ability to achieve an infinite variation in tones.

In this way it becomes possible to blend in tone and outline corrections with the original image in such a way that the handwork becomes almost invisible. This is especially valuable when two or more images have to be combined—the airbrush work here hides joins and abrupt changes of line and tone.

The air brush projects liquid colours on to the paper or other surface in the form of a cone-shaped spray pattern of extremely finely atomized colour by means of compressed air.

The air brush is used by photographers for colouring photographs, working up positives and negatives, introducing cloud effects, removing unwanted backgrounds and general touching-up. It is also very widely used for process retouching, working up litho plates and even for applying gum to photographs.

Other airbrush effects include the emphasis or suppression of selected picture areas, and the introduction of lettering or shadows.

Construction. The air brush is an instrument about the size and shape of a fountain pen. In place of a nib, there is a pointed nozzle with a needle, through which the spray of colour is projected. Immediately behind the nozzle there is a paint reservoir, and behind that there is a control button placed so that the tip of the forefinger rests naturally on it when the brush is held pencil-wise in the hand. Below the control button is a connexion for the flexible compressed air pipe.

The control button can be moved in two directions; it can be pressed down to allow compressed air to enter from the pipe and pass through the air cap, and it can be pressed back

AIR BRUSH COMPONENTS. The essential parts of an air brush are the brush itself A, and the air supply. The latter may be derived from either a cylinder of compressed air B, or an air reservoir D. Such a reservoir would be replenished by a pressure pump C or a foot pump E. In every case a pressure gauge and control valve are desirable to check and regulate the pressure of the supply and so ensure even spraying.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

AIR BRUSH OPERATION. 1. Normally both the air valve from the compressed air supply and the needle valve of the paint reservoir are closed. 2. Pressure on the control button opens the air valve. 3. Pulling back the button opens the needle valve; the compressed air stream carries the paint away from the needle tip in a stream of tiny droplets.

to withdraw the needle controlling the paint supply to the nozzle. By suitable manipulation of the finger button, it is possible to control the covering power of the brush from a fine hairline to a band of colour up to two inches wide.

The normal colour container has a small capacity as the artist rarely wishes to use more than a dozen or so drops of any particular colour at one time. Air brushes with larger colour containers are made for small poster and repetition work.

Water, light oil or spirit colours can be used in the air brush, but all pigmented colours must be finely ground and free from sediment or lumps.

Compressed air for the air brush is supplied by an electrically-driven compressor or a foot pump and is stored in an air receiver at a pressure of about forty pounds per square inch. The instrument is connected to the air receiver by means of a length of flexible rubber hose with suitable connexions to make an airtight joint.

On passing through the air valve, the compressed air goes through air passages to the air cap at the front of the instrument. This air cap entirely surrounds the fluid nozzle, the tip of which lies centrally in the hole at the front of the air cap. When the compressed air passes out through the air cap it drives forward in an expanding cone, at the same time creating a slight vacuum within the fluid tip and sucking colour from the cup along the needle. On mixing with the air stream the colour is atomized into very finely divided particles.

Use. The instrument is held between the index finger and the thumb exactly as a pencil is held, but with the tip of the forefinger resting lightly on the top of the finger button. The nozzle of the air brush should be pointing at about forty-five degrees to the surface to be sprayed whilst the air hose lies naturally across the back of the hand.

To operate the instrument the finger button is first pressed downwards when compressed air immediately passes through the air cap, but no colour emerges. The finger button is now drawn backwards slowly, but still keeping the downward pressure, and the instrument will start to spray colour. The farther the finger button is drawn back, the greater will be the amount of colour sprayed. When ceasing to spray, the finger button must be allowed to go right forward before releasing the downward pressure on it. If this is not done, a particle of unatomized colour will remain in the nozzle and blow on to the paper in a blob the next time the button is depressed.

A certain amount of practice is necessary to enable the user to master precise control of the flow of colour, but once he gets the "feel" of the finger-button action proficiency will quickly follow.

To draw a very fine line, the instrument is held with the nozzle practically touching the paper, but at an angle to allow the released air to escape. The finger button must be drawn back only very slightly, as otherwise far too much colour will be released, and the air brush must be kept moving fairly quickly along the line or the colour will build up to form a blob.

For filling in areas of solid colour the air brush should be from three to four inches from the surface and the area to be covered filled in with steady, even strokes, holding the instrument at the same distance from the surface throughout the operation. Each stroke should overlap half the width of the previous stroke

HOLDING AN AIR BRUSH. Let the instrument rest lightly in the hand, with the airline looped out of the way round the wrist. The index finger operates the control button.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

to obtain an even coverage. As the movement of the air brush ceases at the end of the stroke, the finger button is allowed to go forward to cut off the flow of paint and it is not drawn back again until the brush is starting the next stroke.

Graduated shading is produced simply by controlling the distance the finger button is drawn back in relation to the distance of the brush from the paper. For instance, if the button is drawn back very slightly as when drawing a fine line, but with the instrument some distance from the surface, an almost imperceptible haze is applied which can be graduated right up to solid colour by gradually drawing back the finger button.

It is possible to impart a stippled finish with an air brush simply by reducing the air pressure. This process is particularly suitable for some litho work where a comparatively coarse grain is essential.

Stencils and Masks. For photographic retouching, particularly of engineering subjects where sharp images and good contrasts are required, it is a simple matter to confine the effect of the brush to a sharply defined area by cutting a stencil to mask off the rest of the photograph. These stencils are cut from a special transparent varnish paper which will adhere lightly but firmly to the surface of the photograph. A sheet of the varnish paper is smoothed on to the print and the artist cuts around the outline of the part to be sprayed

SPRAYING WITH MASKS. 1. On a sheet of tracing paper or varnish paper trace an outline of area to be masked from the photograph to be airbrushed. 2. Carefully cut out mask. 3. Lay over area to be protected, register with outline of image, and weigh the mask down with coins or small weights. Finally apply air brush to parts to be sprayed.

SPRAYING CLOUDS. Fluff out a piece of cotton wool of suitable size, hold in position on print with a fork, and spray over surrounding portion. Add modelling after removing cotton wool.

with a very sharp-pointed stencil knife, applying just sufficient pressure to cut through the varnish paper only. The cut-out portion is then lifted out, leaving the required part of the picture exposed.

Some artists prefer to lay a piece of draughtsman's tracing paper over the photograph and draw around the area with a fine pencil. The tracing paper is then laid on a sheet of cardboard and the mask cut out by going over the pencil line with a sharp penknife. This method has the drawback that the mask does not adhere to the surface of the print and, no matter how carefully it is pressed down, there is always a risk that the air pressure will blow colour under the edge and blur the outline of the picture.

Masks used in close contact with the paper give a sharp outline which is suitable for technical subjects, but is generally too hard for normal subjects—e.g., portraits or landscapes. In such cases the mask is traced on to stiff paper or card which can be held away from the surface of the print. The farther the mask is held from the surface when the spray is applied, the softer the outline. This technique would be suitable for darkening the lips in a portrait where a mask in contact would produce an obvious edge.

Compressed Air. The air should be maintained at a regular pressure to ensure first-class work, and it should also be perfectly clean and free from oil and condensed moisture. It is always best to use a compressor designed specially for studio use and to follow instructions given by the manufacturer to drain accumulated water from the air receiver at regular intervals.

Before connecting up the air brush, the air should always be allowed to blow through the hose for a short time to remove any dust particles that may have lodged there. To avoid unnecessary wastage of compressed air, it is essential for the air hose connexions to be screwed firmly on to the nipples provided on the air receiver and air brush. This must always be done with the fingers only; it should never be necessary to use a tool.

Where the air brush is used for a variety of

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

SPRAYING DISTANCE. The farther the air brush is held from the surface to be sprayed, the larger the area covered by the spray. For fine lines and detail hold the brush really close.

processes, it is advisable to have a supplementary air-pressure regulating tank which enables the pressure to be varied from high to low and back again without having to waste time waiting for the air compressor to build up the air pressure.

Air Pressure. Whilst each air brush can be relied upon to do the work claimed for it by the manufacturers, it will be found that each instrument has a certain amount of individuality and no two air brushes are exactly alike in their touch and performance, particularly after they have been in use for some time—one instrument will work best with an air pressure of 28 pounds per square inch, whilst another will need 32 pounds. That is why even in a big studio an artist generally prefers to work with his own air brush.

Cleaning. It is most important to keep the air brush scrupulously clean. If colour is allowed to harden in the fluid nozzle, it will most probably be damaged beyond repair. Immediately after use and whilst the colour is still in a moist condition any colour remaining in the colour cup should be emptied out and replaced with clean water for water colours, turpentine for oil colours or methylated spirit for spirit colours. Any colour adhering to the cup is then removed with a small, stiff brush.

The colour cup is then emptied and refilled with the appropriate solvent and a little is sprayed through the instrument. Next a fingertip is pressed lightly over the front of the air cap and the finger button is depressed and pulled back so that the compressed air is blown back through the front of the fluid nozzle into the colour cup. By agitating the solvent in this way it cleans the fluid passage thoroughly from the cup to the nozzle. It may be necessary to empty the cup and repeat the cleaning process until all traces of colour have been removed from the instrument. Great care should be taken not to spill any liquid into the slot through which the finger button lever works.

If the air cap becomes clogged with dried colour, it is unscrewed from the instrument and cleaned carefully inside and outside with a stiff brush and the appropriate solvent. The hole in the air cap can be cleaned with a splint of soft wood, but on no account should a metal implement be used or it may injure the cap and produce an imperfect spray pattern. When the air cap has been removed, the exterior of the fluid nozzle can be carefully cleaned with a soft rag immersed in cleaning fluid. Fluffy material should not be used for this purpose. When the air cap is replaced, it should be tightened up with the fingers only.

Common Troubles. The following notes indicate the probable causes of the commoner air brush troubles.

Air brush sprays broken line: the trouble may be caused by using too coarse a pigment. It can be prevented by ensuring that the colour is finely ground and filtered through a fine mesh muslin to eliminate any large particles. Thoroughly clean the fluid nozzle, needle and air cap.

Coarse texture line and spray pattern: the air pressure is probably too low. The normal working pressure is about thirty pound per square inch, but it may have to be increased to as high as forty-five pounds when heavy bodied colour is used. This defect may also be caused by holding the air brush too close to the surface of the paper.

Uneven line or one-sided spray pattern: there is probably an obstruction in the air cap which should be removed and cleaned out.

Colour leaking at nozzle when the fluid needle valve is closed: colour has been allowed to dry in the fluid nozzle and must be removed by prolonged cleaning with the appropriate solvent—i.e., water, turpentine or methylated spirit.

Air brush spits during spraying: pigment may have built up on the front of the air cap through using a colour of too thick a consistency or too low an air pressure. Pigmented colour suitable for air brushing should have the consistency of milk.

Air brush spits at beginning and end of each stroke: the instrument is not being used correctly. The finger button must be depressed all the time the needle is drawn back, otherwise colour will be left on the point of the nozzle and blown off as a spot at the beginning of the next stroke.

This defect may also be caused by dirt or solid colour particles on the seating of the needle valve which prevent it from closing completely and allow liquid colour to flow past.

The faults referred to are those that can be dealt with by the user, but any of them may be caused by a defect in an integral part of the air brush, in which case the wisest plan is to return the instrument to the maker for examination.

AIRCRAFT CAMERA

Air photography proper is generally taken to mean the photography of the ground from the air. It has two main purposes: to provide maps and economic information in peacetime and reconnaissance in wartime. There is some overlapping because air survey maps are also made during a war.

Survey cameras tend to resemble one another and show little departure from basic essentials, while reconnaissance cameras take varied forms according to their rôle. Special cameras are used in missile recording.

Common Features. All air cameras must be very robust in construction to stand relatively rough handling and they are generally much larger and heavier than ground cameras. While some of the smaller ones are hand-held, the majority are designed for fixed mounting in aircraft.

In principle the air camera is a rigid fixed-focus high precision instrument designed to take roll films. Operation may be manual but is usually electrically powered, with fast recycling rates and varying degrees of automation.

Formats range from $2\frac{1}{4} \times 2\frac{1}{4}$ ins. to 18×18 ins., the commonest being 9×9 ins. and, on the Continent, 7×7 ins. (18×18 cm.). Films, both perforated and unperforated, from 70 mm. to $18\frac{1}{2}$ ins. wide are used. These are carried in interchangeable magazines holding up to 1,000 feet.

Fast panchromatic emulsions are most common, used in conjunction with a minus-blue filter, but slower types and infra-red are employed for special purposes. Colour is also proving increasingly valuable. These emulsions are usually coated on dimensionally stable "topographic" bases (usually polyester film).

Optical System. Air photographs must provide the best possible definition, so highly corrected lenses are necessary. In particular, the lens must as far as possible be free from distortion. Since the subject is always at infinity, no focusing is required. The lens is fixed permanently at one end of the cone or optical unit; the register glass which defines the focal plane being likewise fixed permanently at the other. The survey camera is required to measure angles between objects on the ground with the precision of a theodolite, and for this to be possible, the optical unit must be rigid with no possibility of relative movement between lens and focal plane once assembled.

The register glass against which the film is located by the pressure plate is a feature of British survey cameras, but American and Continental designers favour a different system in which the film is held flat by vacuum against a rigid flat metal plate while pressed down against a metal frame defining the focal plane. The film should be held flat to 0·0005 in. or better because small departures from flatness which have a negligible effect on definition cause appreciable errors in the map.

The cone is an alloy casting, the locating faces for lens mount and focal plane being machined flat and parallel within fine limits. Diaphragms are often cast on the inside of the cone to keep flare light to a minimum.

In cameras fitted with a register glass this is often engraved with an accurately calibrated grid. By reference to the grid pattern on each picture it is possible to correct for small residual distortions which occur even with survey quality film base.

With a distortion-free lens, rays entering at any angle with the optical axis would emerge on the image side at the same angle, thus the angles subtended at the lens by image points would be exactly the same as those subtended by corresponding objects on the ground. Since no lens is perfect, the camera is calibrated before use by determining the departures from this exact angular relationship at every point in the field and drawing a distortion curve. The lens is set at the focus position which gives best over-all definition, and a value of calibrated focal length is adopted which gives the lowest average distortion over the negative area.

Modern survey lenses have strikingly low distortion figures; in the best examples no image point is displaced from its theoretical position by more than 0·01 mm.

Survey cameras are very commonly used at heights of 15,000–20,000 feet, a 10 foot object then being reproduced by a 6 ins. lens as a patch 0·004 in. diameter. Thus the need for good resolution can be appreciated. Formerly the lens resolution was the limiting factor, even with the somewhat grainy high-speed film normally used. With the best modern lenses this is no longer true except in the outer zones of the field.

Shutters and Image Movement. The exposure time used depends on the speed of the aircraft and the scale of the photograph. Focal plane or diaphragm shutters may be fitted, the former speeded up to 1/2,000 second. Focal plane shutters introduce distortion however, due to the aircraft's forward movement during the shutter blind transit.

Diaphragm shutters are therefore preferable. They are basically similar to those on ground cameras but much larger. The stresses involved in fast recycling over long periods make efficiency and reliability difficult to attain, especially at high speeds and large diameters. Exposure times range between 1/250 and 1/800 second. Certain types of electrically driven disc shutters overcome these difficulties and also give shorter exposures.

Fast shutter speeds freeze image movement on the film. But where this is not feasible, the alternative is to move the film in step with the image. This is the principle of Image Motion Compensation (IMC), embodied in some air cameras or separately in the magazines. The

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

film is moved during exposure, usually by the transport mechanism or by moving the film aperture or pressure platen. Speed of movement is calculated from the aircraft's height and speed and the lens focal length. The image thus stays stationary on the film and longer exposures are possible.

Instrumentation. An increasing amount of information is today recorded on the film rebate. It may include the time, the aircraft's attitude, even its geographical position. It is piped optically to the film from instruments on the camera, and recorded with each exposure. Alternatively, a separate camera, synchronized with the air cameras, may be focused on the pilot's instrument panel.

This information facilitates analysis of the photographs, since it shows exactly what the aircraft was doing when each picture was taken.

Mounting and Installation. The mounting serves to locate the camera positively in the aircraft, to insulate it from vibration and landing shocks, and to provide drift adjustment. The latter is required because the axis of the aircraft does not point along the line of flight, when flying on a given course with any wind coming from the side. In other words, the aircraft moves simultaneously forward (due to its engines) and drifts sideways (due to the wind). So the camera must be rotated about a vertical axis through a corresponding angle to ensure that the edges of the photographs are parallel to the line of flight. Drift adjustment up to 30° may be provided and also some vertical adjustment. The anti-vibration elements are so designed that negligible angular movement is transmitted to the camera during the time of exposure.

Heating is provided to counteract the low temperatures at altitude, by enclosing the camera and photographing through an optically flat window while maintaining a stream of warm air around the installation.

Operation. Air photographs are taken in a series of overlapping exposures. The time interval between them is determined by the aircraft speed and height, format size and focal length of lens. It varies between 1/8 second for fast low-level photography to 2–60 seconds used in high altitude work.

Control may be entirely manual—a release button and stopwatch—ranging to fully automatic from a remote panel. The former is often employed in surveying, the latter in military aircraft where the cameras are often inaccessible.

Operation of the camera throughout the complete cycle is automatic and repeats at intervals determined by setting the control unit. This unit provides electrical pulses at regular intervals, each pulse triggering the shutter, causing the film to wind on and re-arming the shutter ready for the next exposure.

The control unit incorporates a computing intervalometer that triggers the camera electrically. It may also have lens iris, shutter, drift setting and IMC controls, functioning indicator lamps and frame counters. In sophisticated installations many of these settings are monitored electronically and adjusted automatically.

Hand-Held Cameras. Hand-held cameras have few if any of these refinements. Used mainly for taking oblique "pin-points" of single features, they are designed as compactly as possible, protectively cowled and with double hand grips and trigger release for maximum steadiness. Other characteristics are fast lever-wind operation and open frame sights. Maximum film size is about 7 ins., the commonest being 70 mm., usually held in magazines.

Some fixed type air cameras are convertible to hand operation simply by fitting a special mount. Others may be rigid, fixed-focus versions of standard ground cameras and may even take plates.

Most precision ground cameras can still be used for this type of photography, provided they are protected against slipstream and rough handling. Miniature cameras are less suitable, owing to the inherent low information capacity of 35 mm. film.

Survey Cameras. Commercial survey demands the maximum accuracy at the minimum cost. Speed, while important, is not essential, since there is nothing but cost to prevent several attempts being made on one objective. So the most suitable aircraft can be chosen, relatively slow and large, to allow the operator to sit with the cameras and supervise them manually. The cameras themselves are therefore relatively simple.

Since they are required to measure angles between objects on the ground with the accuracy of a theodolite, the cameras must also be of the highest precision. The film must be held flat to 0·0005 in. or better because small departures from flatness that barely affect definition, cause appreciable distortion errors. An accurate grid engraved on the register glass and transferred to each picture helps to correct small residual distortions of the film base. Glass is more stable in this respect, and some survey cameras use plates in a quick-change magazine. Focal plane shutters introduce distortion, and all true survey instruments are characterized by inter-lens shutters.

Modern survey lenses have strikingly low distortion figures, although many are wide-angle objectives. In the best examples, no image point is displaced from its theoretical position by more than 0·01 mm.

Survey cameras are commonly used at heights of 15,000–20,000 feet, a 10-foot object then being reproduced as a patch 0·004 in. in diameter. So resolution is important. Typical values for modern lenses, for low contrast detail on aero type film are 23 lines per mm. axially and 15 lines at the limits of the field.

Apertures do not normally exceed *f*4 for normal and *f* 5·6 for wide-angle objectives.

AIRCRAFT CAMERA. The camera consists essentially of three sections: the cone, the shutter assembly, and the film magazine and transport unit.

Top Left: *Complete camera unit against 1-in. grid to show scale.*

Bottom left: *The main features of the camera (shown without the magazine cover) are A, take-up spool friction; B, counting unit; C, feed spool friction; D, counter arm adjuster; E, gear box assembly of shutter; F, shutter speed adjustment; G, plug block for electrical connexions; H, baffles; I, lens; J, iris diaphragm adjustment.*

Top right: *The main parts of the film magazine are: K, magazine cover; L, pressure plate; M, driving sprocket; N, take-up spool drive.*

Bottom right: *The shutter unit includes: O, hand release button; P, shutter blind; Q, register glass to keep film flat.*

The Camera takes roll film yielding 500 exposures 7½ × 9 ins. and takes interchangeable lenses in detachable cones.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

Some special air survey lenses are corrected for infra-red as well as visible light rays, forming infra-red images in the same focal plane as the visual image.

The standard British and American survey format is 9 × 9 ins., and on the Continent, 18 × 18 cm. In wide-angle survey for maps of scale 1:20,000 to 1:60,000, the lens angle of view is commonly 45° across the semi-diagonal, while for larger scales approximately 30°, is usual. Corresponding approximate focal lengths are 6 ins. and 12 ins. for the 9 × 9 ins. format; 11·5 cm. and 21 cm. for the 18 × 18 cm. image.

Reconnaissance Cameras. Unlike survey, military reconnaissance demands the maximum information in the shortest possible time. Instead of precise angles and distances, the pictures must show what is where. Enemy action may deny any other opportunity than a single high-speed run, covering as much of the target area as possible. This may have to be made at any height from near ground level to the highest possible altitude, often in adverse conditions of weather and light.

Diverse types of aircraft may be used, generally very fast and seldom ideal as camera platforms. At best they may be specially adapted versions of combat aircraft; at worst, standard aircraft modified to carry a camera on occasional photographic sorties.

All these factors profoundly affect camera design. The emphasis is on high output and definition rather than precise operation and dimensional accuracy. Rapid recycling, wide-aperture lenses up to $f1{\cdot}5$ and fast reliable shutters, diaphragm or focal plane, are called for, some distortion errors being acceptable. Since the cameras are often inaccessible to the aircrew, a high degree of automation is necessary. Batteries of cameras may be carried, spread in a fan to cover the widest possible area. These must operate reliably under severe vibration and high "g" (gravitational pulls).

Unorthodox Techniques. Although it is desirable for a reconnaissance camera to do many jobs, the search for greater speed and coverage as well as increased specialization, has led to a wide variety of types and techniques.

A logical development of IMC is the continuous strip camera. This moves the film continuously past a fixed focal plane slit at the calculated image motion compensation speed, making an unbroken record of the ground along the film. Both shutter and intermittent film movement are thus eliminated but a fairly complex control system is needed. Another development is the panoramic camera, in which a rotating prism scans from horizon to horizon across the flight path and records on film moving past a fixed slit in step with it. The camera replaces bulky multiple-fan installations.

To save time, high speed in-flight processing is sometimes used. The film is carried in special magazines in which it is developed and stabilized immediately after exposure. The chemicals are fed into the photographic pastes or on rolls of absorbent material. The developed negatives can be examined on landing or may be scanned by an airborne television camera and relayed to the ground. Alternatively, the television camera may itself record the ground, the transmitted pictures being then photographed.

An extension of this principle is used with satellite cameras, which record on magnetic, electrostatic or thermoplastic tape. This is played back to the ground station at high speed when within range.

Night Cameras. Night reconnaissance cameras normally work on the open flash principle, using pyrotechnic flash bombs or cartridges, for high or low level work respectively. They may have simple capping shutters or no shutters at all, relying on the film transport to move the exposed frames out of the picture aperture and so prevent further exposure. Ultra-wide aperture lenses are fitted, some loss of definition being acceptable.

In a typical low-level installation, a pulse from the control unit advances the film, opens the shutter and fires a flash cartridge simultaneously. After a short delay, the cartridge bursts clear of the picture area, exposing the film and the cycle is repeated. In a high altitude version, the control unit may open the shutter and release a flash bomb which is fused to burst at a given height and clear of the field of view. When the bomb bursts, a photo-electric cell in the aircraft triggers the mechanism for closing the shutter and advancing the film.

Usually the flash cartridges or bombs are contained in ejectors which hold six or more flashes. The flash output has to be of the order of millions of lumen-seconds.

The release of the cartridges, as well as the shutter operation, can still be controlled to take place automatically at pre-set intervals to provide continuous coverage of an area.

Should a flash fail to fire, a further automatic unit closes the shutter again after a specified time.

Missile Recording. Special 16 and 35 mm cine and still cameras are used in radio-controlled target aircraft to record guided missile attacks and measure miss-distances. They are carried in wing-tip "pods" and have ultra wide-angle lenses, sometimes up to 180°, so that several cameras give all-round coverage. The cine types work at framing rates up to 200 f.p.s.; the still cameras sometimes have shutters actuated by small explosive charges. Operation is by radio or radar control.

Such cameras have to be extremely tough, to be recoverable if the target aircraft crashes. Special steps are taken to protect the film and this may take the form of a recoverable or perhaps jettisonable cassette, in which the exposed film is sealed in an armoured watertight casing.

AIR FORCE PHOTOGRAPHY

The primary role of military air photography is reconnaissance; since air forces are the only means available in wartime, another important task is survey. The two rôles often overlap sufficiently to be treated as one. Other uses of photography include the recording of weapon attacks, and a wide range of ground work.

Unlike most civilian air photography, the requirement is normally for quantity of information and speed of delivery rather than photogrammetric accuracy. As much information as possible may have to be gathered in a single sortie, which may be made at any height between ground level and 60,000 feet or over, perhaps in the face of enemy action, in adverse weather or at night.

The aircraft are usually combat types, not designed primarily for photography, although special pilotless "drones" have been developed. The aircraft may be specially adapted for photographic reconnaissance or perhaps only slightly modified for an occasional sortie. They are likely to be very fast and are often unarmed, relying on speed and height for protection. The choice is influenced by the fact that the photographic reconnaissance aircraft must return to base with its films whereas a combat aircraft's mission is completed after delivering its attack.

More than one camera is normally carried, mounted internally or in streamlined "bulges" or pods and photographing through optically flat windows. As they are not always accessible, remote control and automation are needed. Efficient heating is required to keep the film flexible and the lenses and windows clear of condensation, particularly after a fast dive from the sub-zero temperatures at high altitude. Special periscopic sights are fitted to let the pilot aim at the ground below.

Reconnaissance. A characteristic of all air force photography is the amount of logistic support required, both in materials and in trained personnel. This is particularly true of reconnaissance, which may be broadly divided into planning, the photography itself, processing and interpretation. To give some idea of the scale of organization required, a single bomber-type aircraft may carry eight cameras, each with 1,000 feet of film and producing a total of some 10,000 negatives.

The type of operation ranges from long-range strategic reconnaissance of factories and installations deep in enemy territory, to impromptu low-level tactical missions in support of troops. The requirement may be anything from full-scale vertical and oblique coverage of large industrial areas to a few close-range oblique pin-points of enemy positions. This wide range of tasks demands a variety of equipment and techniques. The cameras must be robust high-definition instruments with fast shutters and image motion compensation, and wide-aperture lenses for operation in poor light. Since stereoscopic examination helps interpretation of the pictures, each print must overlap the last by at least 60 per cent; so that fast automatic recycling is needed, particularly at low levels.

A single-seater aircraft normally carries at least two cameras: one vertical and one sideways- or forward-facing oblique. In large aircraft a battery of cameras may be spread in a fan, covering the ground from horizon to horizon. In some cases the cameras are "packaged" by mounting them in interchangeable crates, each designed for a specific task, e.g. high-level, low-level or beach reconnaissance, or survey.

Special requirements lead to special techniques. For long narrow features like roads, beaches, railways, etc., continuous strip cameras may be used. A single panoramic camera can replace the multiple fan, or a small version may be used with a fan to identify the pictures.

Various methods may be employed to ensure the safe and rapid receipt of the pictures. High-speed in-flight processing of the film as it leaves the camera produces negatives ready to print on landing. They may also be scanned in the air by a television camera and immediately transmitted to base. Alternatively, the whole operation may be done by television.

This leads logically to direct recording on video tape, but so far the only reported use of this is in satellites.

Where such methods are not used, the films have to be processed on the ground. Large quantities are handled by rapid continuous processing and printing machines like those used in cinematograph laboratories. Manual processing of smaller numbers can be hastened by printing from wet negatives and by spirit drying, and it is possible for the finished prints to be ready to be air-dropped at a forward position within 15 minutes of landing. All this may be carried out in the field, in specially equipped tents and caravans.

Interpretation extracts the maximum information from the pictures. It is necessary because the identity of objects viewed from the air, particularly from vertically above, is not always apparent. Thus a road bridge may be invisible until viewed stereoscopically or identified by the shape of its shadow, while a vague blur in a single picture assumes shape and size under stereo examination. Other factors are size—found by scaling and measurement—shape and tone (and colour when used). This type of interpretation is done on vertical pictures, backed up where possible by oblique views to add realism and perspective. In cases of urgency, the negatives may be interpreted without printing.

Night Reconnaissance. Air photography in the Royal Air Force is not confined to clear sunny days. Height and speed are normally the only safety precautions that photo reconnaissance aircraft can employ against enemy opposition

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

and, unlike the bomber, its mission cannot succeed unless it lands back safely in its country of origin. Under these circumstances and also because of the need for the immediate assessment of the damage caused by raids and other military operations, night photography plays a most important rôle.

For certain types of subject it is possible to employ an electronic flash produced by releasing through a special tube a condenser charge built up by an engine-driven generator in the course of the outward flight of the aircraft. But so far the pyrotechnic flash holds its own as the best type of illuminant and there is no great difficulty in making flash bombs big enough to cover any target area from any altitude. Unfortunately, as the size of the pyrotechnic charge increases, so does the duration of the flash. Open flash technique is essential, since the entire light output must be utilized, and 1/10 second is about the minimum that can be expected with this type of flash. Again, therefore, the requirements for high-level daylight photography — moving film, anti-vibration mountings, and vertical stabilization—are also essential in successful work at night.

A number of infra-red applications have also evolved from the necessity of photographing at night, in low light and through haze and cloud. The recording of airborne radar is an alternative method, useful in marine reconnaissance and in making radar maps for subsequent blind navigation above cloud.

Survey. Air force survey techniques differ little from those of commercial mapping, except where they are affected by wartime conditions, and in the use of faster aircraft. In fact air forces often assist with peacetime surveys, as with the post war 6 inch-to-1 mile survey of Great Britain. Planning and execution are generally the same as for reconnaissance.

The limits set by aircraft design and performance are just as decisive in low altitude oblique reconnaissance. Aircraft considerably smaller than the type used for high-level reconnaissance are in the main employed for this type of work. These machines are capable of speeds faster than sound and in the design of any photographic equipment carried aerodynamic considerations must be given the first priority. Odd protuberances are out of the question on the surface of a modern fighter aircraft and it may even be necessary to incorporate the outer component of the lens as part of the fuselage of the aircraft. Cameras must be kept as small as possible and since at such high speeds it is impossible for the pilot to gauge the exact instant of exposure, it is desirable to use either a cinematograph camera or at least a camera that will automatically make a series of exposures to "bracket" the target area.

Obviously wartime air survey can seldom be done in conjunction with ground work and it may also have applications not normally met in commercial survey. For instance, it is possible to estimate the depth of water off an invasion beach from air photographs but this would normally be done by surface soundings in peacetime.

The greatest difference lies in the end product. In commercial survey this is usually a map. Wartime requirements are more often for mosaics—photographic maps composed of overlapping vertical pictures, covering a wide area of ground. Mosaics may comprise merely a stack of numbered photographs for the user to fit together or examine separately as necessary, or it may be a large composite picture, each print being cut, fitted together and stuck down on a mount, together with scales, compass directions, etc.

The final refinement, used in briefing for major operations, etc., is the three-dimensional terrain model. It is built up on a solid contoured base derived from stereo measurements, coloured and equipped with model trees, houses and other features.

Strike Recording. An important photographic task in any air force is recording weapon attacks, both "live" in action and simulated in practices.

The best-known application is the cine camera gun, usually a 16 mm. camera, aligned with the aircraft's guns and operated by the firing button. In war, the films help to substantiate claims of damage; in training, they take the place of live ammunition and permit assessment of results. The same cameras or larger 35 mm. or 70 mm. versions are used to record dive-bombing and rocket attacks and practices.

The cameras run at speeds from 8 to 120 frames per second and are designed to overrun for a few seconds after release of the firing button, to allow time for the last round to reach the target. Since the pilot starts violent evasive action during this period, wide-angle lenses are needed to keep the target within the field of view.

Strike cameras may also be mounted in radio-controlled target aircraft (drones). Such cameras are usually cine instruments with wide-angle lenses, mounted in specially robust pods to protect the camera if the target craft crashes. Sometimes the film magazines are armoured to preserve the film for processing and evaluation even when the rest of the aircraft (and camera) breaks up completely on impact.

High-level bombing is recorded with standard vertical air cameras. Where cloud, smoke or debris obscures the target, a separate reconnaissance must be mounted subsequently.

Again, this branch of military photography is supported by a closely-integrated ground organization for maintaining and reloading the cameras, processing films and assessing the results as quickly as possible.

Ground Photography. Apart from aerial work, much of the air force photographer's time is taken up with ordinary ground photography, covering many aspects of commercial and industrial work. It includes portraits for identity

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

cards, instrumentation and oscilloscope record ing, press and publicity material, and the production of full-scale training films, often involving animation and slow-motion photography.

Photographs are required of all damaged aircraft parts and of the scenes of accidents, even of routine evolutions. In the Royal Navy for example, every individual landing on an aircraft carrier is recorded on 16 mm. film, often supplemented by still cameras. The results have proved invaluable in assessing the causes of accidents. P.B.M. & R.W.B.T.

AIRGRAPH. Letter transmitted as a microfilm copy from which the receiver was given an enlarged print; chiefly used during World War II.

See also: *Microcopying.*

AIR PHOTOGRAPHS. Photographs can easily be taken from aircraft using equipment normally employed for outdoor work with little or no modification.

Amateur Pictures. The view from the windows of airliners is not always good, but, with luck in getting a seat and clear weather, quite reasonable records of a flight can be obtained with small hand cameras. If the photographer is fortunate enough to fly in a private aircraft, the view will be better and the scope for composition correspondingly greater.

Photography should only be attempted when close to the ground, say 1,000 feet or lower, unless another aeroplane or a striking group of clouds or mountains forms the motif of the picture. While the choice of apparatus is not critical, a direct vision finder is to be preferred, panchromatic film and, under good atmospheric conditions, a pale yellow filter are usually best. Shutter speeds of 1/100 second or slower should not be used. Exposure may be calculated as for distant landscapes, but a meter is preferable. Development should be for high contrast. Colour work can be done quite successfully, but an ultra-violet absorbing filter or haze filter is almost essential.

Yellow, orange, or red filters may be needed for black-and-white photography to eliminate haze.

Vibration may be a problem, and the camera should not be rested on window frames, etc. Airliners are not normally troubled by bumpiness, but the smaller aircraft will present problems in turbulent weather, and the proportion of successful shots may be small. The larger airliners usually experience the greatest bumpiness when at low altitudes—soon after take off and just before landing—which are usually also the best times for air to ground photography; this kind of turbulence is, however, seldom sufficiently serious to prevent the production of sharp photographs with the use of a fast shutter speed. Photography from open cockpit aircraft calls for considerable skill and some thought should be given to protection of bellows cameras against the force of the wind.

Before attempting photography from airliners, the amateur should verify that this is not forbidden by the regulations of the country over which the aircraft is flying.

Press Pictures. By logical extension the same approach would serve for occasional professional work of a pictorial, press, or record kind, yielding pictures with a broadly pictorial motif or news interest such as appear regularly in the press. These are taken for general interest and are not essentially different in technique or outlook from ground photography, nor do they account for more than a small fraction of all the film exposed in aircraft. Hand-held cameras are manufactured especially for this class of work. They have some of the features of the aircraft camera proper, such as rigid construction, absence of focusing, shutter for short exposures only, but are usually smaller and adapted for use in the hand.

An essential characteristic of all these pictures is that they show the scene in normal perspective, as it would be seen from the side window of the aircraft. Features appear in much the same spatial relationship as seen from the ground; the horizon may be visible; at least we can feel where it should be. The camera axis, in fact, has been at some small angle with the horizontal; in technical terms the photographs are obliques. The more important class of air photographs, however, is that taken with the camera axis pointing vertically downwards —known as verticals.

For certain purposes oblique photography also may be used in mapping and for military reconnaissance, but as there the scale varies across the picture verticals are more usual.

Vertical Photographs. To the uninitiated, the vertical air photograph is often meaningless because it shows the landscape in an unfamiliar aspect—the map view. Perspective is almost entirely absent because the objects are all clustered near to a mean plane, the earth's surface, which is usually at a great distance from the camera. Yet such photographs are of immense value in peace-time and military value in war, for map making and reconnaissance, because the scale is uniform across the picture, and because they contain a complete catalogue of all visible details on the piece of ground shown and indicate the exact location of each with respect to the others.

The positioning is not confined to two dimensions; if two shots taken immediately after each other are viewed in a stereoscopic viewer, the pictures leap to life in a startling manner,

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

with every house and tree standing up realistically and every contour of the ground clearly displayed. By measurements taken from an accurate stereoscopic record, it is possible to draw a map in both contour and plan. G.C.B.

Books: *Aerial Photographs and their Applications*, by H. T. U. Smith (New York).

AIR-TO-AIR PHOTOGRAPHY. Photographing an aeroplane in flight from another aircraft, or air-to-air photography, is highly specialized work calling for close co-ordination between the two pilots and the photographer. Air-to-air photographs were formerly taken from the passenger seat of an open two-seater, the camera sometimes being held in the slipstream. Nowadays the photographer can work in comfort through the open window of a cabin aircraft, but frequently he is handicapped by the great disparity of speed between such aircraft and the modern high-speed jet-propelled types, which he may be called upon to photograph. The high altitudes at which these sometimes operate necessitate a pressurized cabin, the windows of which may consist of a double sheet of Perspex, destroying definition in a photographic negative. Thus, though the speed of sensitized materials has kept pace with that of aircraft, the design of the latter no longer provides a vantage point for a photographer, who is therefore still obliged to use the slower machine. This greatly limits his freedom of action and choice of viewpoints.

Camera. Owing to the limited demand, there are only a few special "air-to-air" cameras on the market, although other cameras are, in limited quantities, adapted to the appropriate specifications. Cameras constructed for air-to-ground work are not suitable. For casual air-to-air work the normal direct vision type of press camera, taking $2\frac{1}{2} \times 3\frac{1}{2}$ or 4×5 ins. negatives, is quite suitable, as is also the single lens reflex type of camera, preferably in the roll-film size. When flying in an open aircraft, any bellows on a camera should be replaced by a suitable solid box. Air-to-air cameras usually are of rigid design with hooding cones to protect most of the camera controls against wind pressure. Interchangeable lenses may be provided. Some models take magazines of 70 mm. film for 50 or so exposures, obviating the need for frequent film changes.

Photographer's Aircraft. The aircraft from which the photographer is to work should have a speed comparable to that of the target aircraft and afford good vision. Speeds vary so greatly that the target aircraft may be stalling while flying faster than the maximum speed of the photographic aircraft. Under these conditions there is little time to compose the picture, and success depends on a combination of experience and luck.

In airliners having the engines, whether jet or piston, mounted on the wings in the conventional manner, the best camera position is in front of the wings. At any point behind the wing the heat trail of the exhaust from the engines will render the image unsharp on the film. If the only available seats on an aircraft are rear ones, it is best to take one as far back as possible, to shoot toward the tailplane, rather than in a forward direction.

The most suitable of all photographic aircraft is the now obsolete four-engined bomber with tail turret. Seated in the turret, the photographer has an angle of view of almost 180° in both horizontal and vertical planes.

The Subject. Air-to-air photography is a combination of portrait, landscape and high-speed photography, with the target aircraft as the model and the background constantly changing. The background should be chosen to suit the aircraft—e.g., clouds for a bomber, coastline for an airliner and sea or a ship for a naval machine.

Technique. In air-to-air photography at least three people are involved: the pilot of the photographer's aircraft, the pilot of the target aircraft, and the photographer. They must work as a team, and it is desirable for the pilots to have previous experience of this form of flying. It is also a help if the pilot of the photographic aircraft has an eye for a picture.

Work on a photographic sortie begins with briefing before take-off. A complete plan of the intention and order of execution should be arranged. If this is not done failure may result and flying time be wasted. This is important with large modern aircraft, which may cost hundreds of pounds for every hour they are in the air.

Once the team is airborne, inter-communication between pilot and photographer is essential, and radio communication between the pilots almost as important.

When the target aircraft is in close formation the lighting should be carefully studied before an exposure is made, and in case of need the pilot asked to alter course to effect an improvement. He can also pass messages to the pilot of the target aircraft, requesting alterations of relative position; or this can sometimes be done by hand signals. While a skilled pilot can reduce speed of a target aircraft flying singly for the benefit of the photographer, this is impossible in formation flying, and the photographer will have to take quick decisions when a picture presents itself.

Camera Manipulation. Fast panchromatic plates or films are used, and with a $2\times$ or $3\times$ yellow filter a lens aperture of $f8$ will provide well-exposed negatives on most occasions even at high shutter speeds. Except for special effects, over-correction of skies with orange or red filters is not recommended. In very intense light above clouds it is advisable to allow sufficient exposure so as to permit soft development, otherwise the negatives will be harsh.

CC-0. Agamirgam Digital Preservation Foundation Chennai

When working with the camera at the aircraft cabin window, it must on no account be held out into the slipstream, as it will be wrenched away by the force of the air blast. The photographer must never allow the camera itself, or his elbow, to touch the aircraft during an exposure or the vibration will spoil the definition of the negative. C.E.B.

See also: *Air Force photography; Air photographs.*

AIRY DISC. Central area of the image of a point source of light focused by a lens free from aberrations. The Airy disc is surrounded by concentric rings of light of feebler intensity which can in practice be ignored. The effect is an optical phenomenon connected with the wave nature of light and is called after its discoverer, G. B. Airy, Astronomer Royal in 1830.

ALBADA FINDER. Direct vision optical viewfinder devised by Van Albada in which the picture area is indicated by a white outline apparently suspended in space. This viewfinder is useful in sports photography. Present bright-line finders work on a similar principle.

See also: *Viewfinder.*

ALBERT, JOSEPH, 1825–86. German photographer. Made collotype commercially practicable in 1868, introduced as Albertype.

ALBERT EFFECT. Particular type of image reversal produced by treating an exposed plate with dilute chromic acid and then exposing it to white light. Subsequent development brings up a positive image formed on the grains which were not affected by the initial exposure and bleaching process.

ALBUMEN. Complex organic compound at one time much used in photography for making albumenized paper—an early type of daylight printing paper. For this purpose it was prepared from the white of egg, which is almost pure albumen.

ALBUMEN-ON-GLASS PROCESS. The first practical photographic process on glass, made public in 1848 by Abel Niépce de Saint-Victor. The glass plate was coated with white of egg containing potassium iodide. When dry, the plate was sensitized with an acid solution of silver nitrate and, after exposure, developed with gallic acid. Very fine detail was obtained, making the process excellent for architecture and art reproductions, but the exposure—5 to 15 minutes, according to circumstances—was far too long for portraiture. Albumen positives were widely used for lantern slides and stereoscopic pictures until about 1857.

See also: *Hyalotype.*

ALBUMEN PAPER. Glossy positive printing paper introduced by L. D. Blanquart-Evrard in 1850, in general use until *c.* 1900. The paper was coated with a solution of albumen and an ammonia salt in rectified spirit and then sensitized with silver nitrate. It was usually toned with chloride of gold to improve the colour and permanence of the picture. With the exception of the inventor, who developed his prints, it was used as a printing-out paper.

See also: *Sensitized materials history.*

ALBUMS. An album is the most convenient place for keeping a collection of photographs so that they can be looked at without being handled. It displays the prints while keeping them clean and free from creases.

The simplest form of album is just a book with stiff covers and blank pages. Prints are stuck in position with adhesive on each page. There are just enough pages to take up all the space between the covers when the album is full.

Loose Leaf Types. Loose-leaf albums allow the removal or insertion of pages. One of the most convenient types has the pages attached to the spine of the cover by split metal rings. This type lies flat when open.

Albums are available with both vertical and horizontal formats and in a wide range of sizes. The covers may be finished in materials like decorative cardboard, fabric or leather. For special subjects—e.g., collections dealing with a single event or a particular period—covers can also be bought ready embossed in silver or gilt with suitable titles such as "Our Wedding," "Baby" and "Summer Holidays." In addition to the title the subject may be indicated by mounting a representative photograph or a cut-out on the cover.

There is usually a choice of black, grey or white pages, but it is advisable to buy only

MOUNTING IN ALBUMS. Top left: *Mounting a print with gummed corners.* Top right: *Slits cut into the album page itself hold the print in a fixed position.* Bottom: *Double gummed corner pieces are a further alternative.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

those made specially for photographs. In ordinary paper there may be impurities which in time will stain or bleach the print.

Doubled-over celluloid or plastic pages are also obtainable to hold slip-in prints of the same size.

Mounting the Prints. There are several ways of mounting the photographs. Some albums have diagonal slits in each page, four to a print, so placed that the corners of the print can be slipped into the appropriate slits. With this system prints can be mounted on one side of the page only, and only prints of standard sizes can be used unless fresh slits are made. This system is now little used.

A more popular method is to use small adhesive corner pockets. These can be stuck to the page to accept the corners of any sized print; they are cheap to buy and are sold gummed ready to use. Another idea is to use paper corner pieces gummed on both sides so that they can be first stuck to the print, and then to the page.

When large prints are to be fixed to a page permanently, the use of dry mounting tissue is best. This would be appropriate in the case of weddings, where each print occupies a page.

Titling. It is usual to add captions or titles to each picture. Special white ink is made for titles on black or grey paper; ordinary Indian ink is suitable for white pages. In general, it is better to keep the captions brief and factual, giving only the essential information of who, where and when. Clever or literary captions are best avoided, as is also fancy lettering.

J.D.C.

ALCOHOL. Used as a solvent in varnishes, for rapidly drying negatives, also used in certain processing solutions which contain substances not easily soluble in water.

Formula and molecular weight: C_2H_5OH; 46.

Characteristics: Colourless liquid with faint pleasant smell.

Solubility: Mixes with water in all proportions.

Ethyl alcohol (above formula) is available in several pure forms (absolute alcohol, rectified spirit) and also in denatured versions (i.e., with additions to render it unfit for drinking and so exempt it from excise duty), such as industrial methylated alcohol (colourless), and the common purple methylated spirits.

In addition there are a large number of other alcohols of which methyl alcohol (CH_3OH, wood spirit) is sometimes used in photography.

All these kinds of alcohol mentioned above (except for the purple methylated spirit) can be used in photography.

ALDEHYDE. Term in chemistry denoting a compound containing the group CHO, e.g., formaldehyde, the aldehyde of formic acid. Formaldehyde hardens gelatin.

ALKALI. In chemistry, the term alkali is applied to a number of soluble metallic

ALKALIS COMPARED

Alkali	*Other Names*	*Formula*	*Solubility at Normal Temperature*	*Alkalinity*
Sodium carbonate	Soda ash	Na_2CO_3	Freely soluble	Medium
Potassium carbonate	Potash	K_2CO_3	Highly soluble	Medium
Sodium hydroxide	Sodium hydrate, caustic soda	NaOH	Highly soluble	Very high
Potassium hydroxide	Potassium hydrate, caustic potash	KOH	Highly soluble	Very high
Borax	Sodium tetraborate	$Na_2B_4O_7$ $10H_2O$	Slightly soluble	Low
Borax plus boric acid	—	—	—	Very low

Sodium sulphite	—	Na_2SO_3	Fairly soluble	Low

*Alkaline solutions with a high buffering action change little in pH with appreciable variations of concentration.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

hydroxides, with certain definite characteristics, e.g., they turn red litmus blue, they feel soapy, and they react with acids to form salts. Metals which form such alkalis are known as the alkali metals, while salt solutions with similar characteristics are termed alkaline.

The degree of alkalinity of a solution is measured by its pH value; all values above 7 are alkaline and the higher the figure, the stronger the alkali.

The term has a special application in photography where it refers to an important constituent of the developer. Most developers must contain an alkali because they will only work in alkaline solutions. The alkalinity of the developer solution greatly influences its activity and development speed. The more strongly alkaline (i.e., the higher the pH value) the more energetic the developer.

There are, however, some developing agents which can work in nearly neutral or even slightly acid solutions, i.e. with a pH below 7.

How alkaline a solution is, depends mainly on the concentration, and to some extent on the nature, of the alkali.

Generally, the more alkali a solution contains, the higher its pH value. Some alkalis, like sodium or potassium hydroxide solutions, change greatly in pH when the alkali concentration is slightly varied. Developers containing these alkalis rapidly lose their activity in use and are soon exhausted, since the alkali concentration and hence pH value rapidly drops as the alkali is used up.

Other alkalis, like sodium carbonate or trisodium phosphate solutions, change their pH much more gradually in certain ranges as their concentration varies. They have some alkalinity in reserve which is brought out when the concentration decreases. The reason is that these alkalis form a very small amount of sodium hydroxide when they are dissolved in water. As this hydroxide is used up, more is formed all the time. They thus behave like very weak solutions of sodium hydroxide which remain more or less constant during use.

Substances like sodium carbonate are strictly speaking salts of a weak acid—that is why they behave as if they were proper alkalis.

In effect not all of the alkali in the solution comes into action simultaneously. Hence the pH value—the real hydroxide (actually hydroxyl ion) concentration remains nearly the same as long as there is enough alkalinity reserve left to trickle through all the time.

This property is particularly marked with certain mixtures of alkalis (strictly speaking alkaline salts in equilibrium with an acid form)—the so-called buffer solutions. Such developers lose their activity much more slowly.

The alkalis sodium or potassium hydroxide are commonly used for energetic developers, and sodium carbonate for normal formulae.

Sodium carbonate is used in three forms: anhydrous, monohydrate (chiefly in the U.S.A.) and crystalline (decahydrate). These (like the two forms of sodium sulphite) con-

ALKALIS COMPARED

*Buffering Action**	*Use*		*Remarks*
	High Concentration	*Low Concentration*	
Very high	Most normal negative and positive developers	Some fine grain formulae	Exists in several forms; anhydrous, crystals, monohydrate
Very high	A few normal developers	—	Very hygroscopic
Nil	High contrast and high energy developers	—	Deliquesces; must be kept sealed in bottles
Nil	High contrast and high energy developers	—	Deliquesces; must be kept sealed in bottles
Moderate	—	Fine grain developers	—
Very high	—	Fine grain developers	—
High	Normal developers	Fine grain developers	*Kodalk* is a proprietary metaborate alkali
High	—	Fine grain developers	—
Very high	—	Fine grain and low energy developers	Typical buffer mixture
Moderate	Fine-grain and low-energy developers	Colour developers	Also acts as preservative

The pH of solutions with low buffering actions changes greatly with small variations of concentration.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

tain varying amounts of water of crystallization. They are freely interchangeable.

EQUIVALENTS OF SODIUM CARBONATE

Decahydrate Crystals $Na_2CO_3.10H_2O$	Monohydrate $Na_2CO_3.H_2O$	Anhydrous Na_2CO_3
100 parts	... 43½ parts	37 parts
230 parts	... 100 parts	86 parts
270 parts	... 117 parts	100 parts

One disadvantage of sodium carbonate as an alkali is that it gives off carbon dioxide gas when it is neutralized (e.g., in an acid stop bath). As the carbon dioxide is formed within the emulsion layer, it can cause blisters both on negatives and on prints.

Milder alkalis, like weak solutions of borax, or sodium metaborate, are used in low energy fine grain developers. Even sodium sulphite by itself acts as an alkali.

Substances like triethanolamine, and combinations of sodium sulphite and formaldehyde or acetone have also been used. L.A.M.

ALPHA PAPER. Obsolete name for gelatine chloro-bromide paper introduced by J. M. Eder, January 1883, and produced by Marion & Co. of London under this name, 1884.

ALPHA PARTICLE. Positively charged particle—in fact a helium atom nucleus—with a velocity of about 1/12 to 1/20 that of light, emitted by radioactive substances. The path of the particle can be recorded in specially made photographic emulsions—a technique which has important applications in nuclear research.

See also: *Nuclear physics.*

ALPINE PHOTOGRAPHY. Another name for photography of mountains and mountain scenery that has probably come into use because of the popularity of Switzerland as a holiday resort. But the photography of Alpine scenery is no different from that practised in any other mountainous country.

See also: *Mountains.*

ALTERNATING CURRENT (A.C.). Electric current produced by a potential which is constantly and regularly varying between zero and a maximum, alternately positive and negative.

Electricity generated by an alternator. Most of the public electricity supply in Great Britain is alternating current.

ALUM, AMMONIUM. Ammonium aluminium sulphate. Sometimes replaces potash alum as hardener in fixing baths.

Formula and molecular weight: $NH_4Al(SO_4)_2.12H_2O$; 453.

Characteristics: White crystalline salt.

Solubility: Fairly soluble in water at room temperature.

ALUM, CHROME. Potassium chromium sulphate. Hardener in stop baths and fixing baths.

Formula and molecular weight: $KCr(SO_4)_2.12H_2O$; 499. Ammonium chrome alum $NH_4Cr(SO_4)_2.12H_2O$ is similar.

Characteristics: Violet crystals forming a purplish solution. When heated, or in the presence of sulphite, the solution gradually turns greenish and loses its hardening properties.

Solubility: Fairly soluble in water at room temperature.

ALUMINIUM AMMONIUM SULPHATE. Chemical sometimes used as a hardener in fixing baths.

See also: *Alum, Ammonium.*

ALUMINIUM CHLORIDE. Often used in concentrated liquid hardener solutions.

Formula and Molecular weight: $AlCl_3$; 133.

Characteristics: white crystalline powder usually caked into lumps because of strong deliquescence. Fumes of hydrogen chloride.

Solubility: very soluble in water and is usually handled as a concentrated liquor of 25–30 per cent AlCl3.

ALUMINIUM POTASSIUM SULPHATE. Chemical commonly used as a hardener in fixing baths.

See also: *Alum, Potash.*

ALUMINIUM SULPHATE. Possible substitute for the alum hardeners.

Formula and molecular weight: $Al_2(SO_4)_3.18H_2O$; 666.

Characteristics: White crystals with sweet, astringent taste.

Solubility: Highly soluble in water.

ALUM, IRON. Ferric alum; ferric ammonium sulphate. Chemical used in certain toners and reducers.

Formula and molecular weight: $NH_4Fe(SO_4)_2.12H_2O$; 482. Ferric potassium sulphate $KFe(SO_4)_2.12H_2O$ is similar.

Characteristics: Purplish crystals, give a yellowish solution.

Solubility: Highly soluble in water at room temperature.

ALUM, POTASH. Potassium aluminium sulphate; potassium alum. This is the common alum. Used as a hardener in fixing baths.

Formula and molecular weight: $KAl(SO_4)_2.12H_2O$; 474.

Characteristics: Colourless crystals or crystalline powder.

Solubility: Fairly soluble in water at room temperature.

AMATEUR PHOTOGRAPHY

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Potentially creative, amateur photography gets closer to being the folk-art of the twentieth century than other contemporary media, e.g., radio, cinema, television. Its popularity is international; the interest and diversity of its applications almost unlimited.

Not only does this variety of application defy all attempts at a common definition but it also leads to frequent protests from some amateurs against being classed with some others. One amateur may very much differ from another in respect of the degree to which he cultivates his hobby, the subject matter, mode of expression and techniques he is attracted by and his relative freedom from financial limitations.

There are people who expose only a few rolls of films during their holidays and leave the processing to a dealer. There are others who very regularly devote a great deal of time to photography and so become experts at many aspects of it. Between these two extremes there are numerous groups, intermediate in experience, enthusiasm and purpose. The flag-bearers of amateur photography will be found organized in clubs, societies and associations. They are the people most consistently concerned with pictorial quality and technical progress. They read periodicals, frequent lectures, participate in exhibitions and foregather at congresses. Many brilliant amateurs, of course, remain lone workers and will not join in any of these activities. In fact the membership of Great Britain's approximately 3,000 amateur organizations has been estimated to be no more than a fraction of 1 per cent of the number of people who take amateur photographs in this country. Yet, in Britain as well as in other Western countries, the organized amateur movement speaks for all amateurs, even if it may not be truly representative of them. The photographic industry, to whom the more vociferous elements in the clubs may occasionally cause a little inconvenience, nevertheless makes every effort to keep the movement happy and active because of its importance as a testing ground and listening post.

Types and Interests. Both within the organizations and outside of them there is a legion of different types following as many different fields of interest. There are amateurs producing fine pictures without preference to specific subjects and there are others who are all the time after some specific subject putting pictorial excellence second. There are amateurs who pride themselves on advanced technical skills and there are others who prefer to explore the theoretical backgrounds of the very same techniques. There are die-hard perfectionists and there are restless experimenters. There are disciplined followers of "schools" and there are eternal controversialists. There are ardent collectors of all types of equipment and there are untiring inventors of home produced gadgets (which once made may never be used). There are plenty of photographic enthusiasts who never succeed in making a reasonable picture and some who would not even attempt to take one. There are many Royal or otherwise distinguished amateurs and masses of very ordinary ones. There are youngsters accustomed to handle a camera even before they have learned to read or write and aged people still taking pictures with their eyesight almost gone.

The economic background to amateur photography is also enlivened by varied patterns and peculiarly contrasting elements. Probably dominant is the fact that people are not sensible about their hobbies, and their habits of spending money on them are governed to a greater degree by their enthusiasms than their circumstances. At least at periods of economic crisis the average man is comparatively slower in cutting down on his hobbies than on daily necessities. Of course people have been known to give up photography altogether but more often than not it grows on them. This is particularly true between the ages of 20 and 30 when courting, young family life, travel and sport may provide the initial stimulus. In Great Britain, within this age group, sixty-seven people in every hundred took photographs in 1951. Once a person, often to his own surprise, has succeeded in taking a few genuinely good photographs the chances are that he will acquire a taste for the sheer creative satisfaction gained in the process. As his enthusiasm grows so will his expenses and he may try to make his hobby pay for itself. So it is by no means uncommon for amateurs methodically to follow cash prize competitions or even to freelance, employing the winnings and profits to acquire better equipment and more material.

Vice versa, there are well-known professional photographers who enjoy using their cameras to occupy their leisure in an amateur capacity. These participate in predominantly amateur events and take an active part in the life of amateur organizations. In fact, many leading figures of the amateur movement are professionals. Editors of photographic periodicals, authors, lecturers, scientists, technicians and even business executives of the photographic industry have, with a varying degree of justification, claimed to be "only amateurs". It is hard to know where to draw the line and, in any case, probably quite unnecessary to do so.

Contributions to Progress. There always has been a busy two-way traffic between amateurs and the business of photography. A number of basic inventions originated with amateurs. Richard L. Maddox, M.D., who made the first silver bromide emulsion and the dry plate and yet never received any financial benefit, is a

CC-0. Jangamwadi Math Collection. Digitized by eGangotri Digital Preservation Foundation, Chandigarh

classic example. Yet isolated magnates like this illuminate as little the importance of amateurs to photography as does the equally marginal fact that amateurs were the first photographic book illustrators, that they pioneered in geographical and architectural exploration with the camera, that new applications of photography to scientific research are still more likely to be initiated by amateurs than by professionals.

A more typical impact of amateurs on photography, of an altogether different order, became first apparent on the introduction for sale of ready-made dry plates. Professor Herman W. Vogel, who produced the orthochromatic emulsion, tried to quell the alarm of professional photographers by saying, "Not everybody who got hold of a violin is as yet a violinist and not everybody who got hold of a dry plate is as yet a photographer." But it is much easier to take a picture than to play the fiddle—as events were soon to prove. These events followed and later repeated a familiar cycle; first, simplification of technique spread photography among amateurs; secondly, masses of amateurs applying the new techniques in new ways upset the prevailing patterns of professional photography. This is exactly what happened after 1880 when dry plates in the hands of amateurs marked the beginning of pictorial photography; again after 1900 when film and light-weight hand cameras brought with the "snapshot" the fashion of informal photography; and more recently, since the 1930's, when precision-made cameras, high-speed lenses and fast panchromatic materials turned first amateur and then professional photography into an ever present and candid tool for recording life as it is. In the 1960s trends towards a contempt of "technique" and in particular a deliberately careless play with colour often originated with amateurs or at least with very young people with a camera who have not as yet settled into patterns of established professionalism.

The importance of the part played by amateurs in all these developments is not so much due to the merits of particularly gifted individuals or even the spirit of freedom permeating any activity unhampered by commercial consideration as simply to numbers. Manufacturing equipment and materials for hundreds of thousands of amateur consumers is a very different proposition from producing tools for a few hundred professionals. The competitive element, tempted by an ever expanding market, stimulates ideas, accelerates research and makes it a practica proposition to tool up to high quality standards. Thus the amateur's greatest gift to photographic progress is, in fact, mass consumption.

Purchasing Power. According to the United States Department of Commerce the value of photographic materials supplied at manufacturers' prices in 1961, exceeded 1,269 million dollars. The estimated figure for 1962 exceeded 1,362 million dollars. Thirty-four per cent of this output went to the amateur market (as compared, according to the U.S. National Association of Photographic Manufacturers, with 28 per cent to professional and industrial users, 13 per cent to the motion picture industry, 14 per cent to blockmakers and printers and 11 per cent to medical institutions). Over and above this figure, amateurs fired off in 1961 39 million dollars worth of flash bulbs, in 1962 an estimated 43·7 million dollars worth (at manufacturers' prices) as well as paying for 390 million dollars worth of developing and printing services in 1961 and an estimated 385 million dollars worth in 1962 (at retailers' prices).

In the United States and in Great Britain at least every fourth person has a camera, in Germany nearly every fourth. Camera ownership in Japan is—at least in the bigger cities—also reaching similar proportions. In the countries without a photographic equipment industry of comparable output, however, fewer people tend to own cameras. At the beginning of the 1960s large previously untapped markets were opened up by the introduction of increasingly automated low-price cameras.

In the United States at present nearly 670 million flash bulbs are consumed per year, in Great Britain probably less than 30 million. But the price of a flash bulb in the United States is less than that of a Sunday paper, in Great Britain it is equal to that of two Sunday papers.

American amateurs in 1962 made 2,300 million pictures, 43 per cent of them in colour; British amateurs took some 500 million pictures in 1963, about 30 per cent in colour.

The uneven distribution of the photographic industry coupled with restrictive international trading practices inevitably leads to uneven progress of amateur photography in various countries. While this is regrettable and perhaps unfair, the steady advance of amateur photography in those countries where it is not handicapped is an encouraging signpost on the road towards a brighter future everywhere in the world. A.K-K.

AMBROTYPE. Under-exposed collodion on glass negative which appears as a positive when backed with black varnish, black paper, etc. A variant of the collodion process; devised by Frederick Scott Archer in collaboration with Peter W. Fry in 1851. Mainly used for portraiture as a cheap substitute for the daguerreotype. Collodion positives on glass are called Ambrotype in England and the United States, and Melainotype on the Continent of Europe.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

AMERICAN SOCIETY OF MAGAZINE PHOTOGRAPHERS. Society established in 1945 (and now having world-wide membership), "to safeguard and promote the interests of magazine photographers, to maintain and promote high professional standards and to cultivate friendship and mutual understanding among professional magazine photographers."

The ASMP is incorporated as a labour union to enable it to work more effectively for its members. Since 1950 the activities of the Society have broadened to include all forms of photography for publication, including advertising. The ASMP acts as a clearing house for information on rates, practices, market conditions. Its *Code of Minimum Standards*, established in 1951, has become accepted by the industry as a minimum scale for editorial work.

Monthly meetings are held in New York, Los Angeles and San Francisco. From time to time the Society sponsors exhibitions, conferences and symposia.

The Society publishes a directory of its members twice yearly and also an illustrated monthly magazine, *Infinity*, sold by subscription and on a single issue basis. A confidential bulletin for members only contains technical, market and other information of interest. The ASMP has also published three distinguished photographic annuals, *Photographic* 1949, *Picture* 1957 and *Picture* 1960.

AMIDOL. 2 : 4-diaminophenol hydrochloride. A developing agent.

Formula and molecular weight: $C_6H_3OH(NH_2HCl)_2$; 197.

Characteristics: Whitish grey powder; keeps well in air-tight bottles, but slowly turns brown in the air. Solutions do not keep, therefore dissolve amidol just before use.

Solubility: Freely soluble in water at room temperature.

AMMONIA. Used in solution in the form of ammonium hydroxide; also in gaseous form for dry development of certain types of dyeline materials.

Formula and molecular weight: NH_3.17.

Characteristics: Colourless gas with a pungent smell.

Solubility: A saturated solution in water contains approximately 308 grams of gas per litre and has a specific gravity of 0·880.

AMMONIUM ALUM. Chemical sometimes used as a hardener in fixing baths in place of potash alum.

See also: *Alum, Ammonium.*

AMMONIUM BICHROMATE. Ammonium dichromate. Used in sensitizers for the carbon, carbro, and gum bichromate processes.

Formula and molecular weight: $(NH_4)_2Cr_2O_7$; 252.

Characteristics: Orange crystals.

Solubility: Freely soluble in water at room temperature.

AMMONIUM BROMIDE. Restrainer in special warm tone developers, also in certain bromide paper emulsions.

Formula and molecular weight: NH_4Br; 98.

Characteristics: White crystalline solid; hygroscopic.

Solubility: Highly soluble in water at room temperature.

AMMONIUM CARBONATE. Alkali in special warm tone developers.

Formula and molecular weight: $(NH_4)_2CO_3$; 96. The substance sold as ammonium carbonate is often a mixture of ammonium bicarbonate and carbamate, which acts very much like the carbonate.

Characteristics: White waxy cubes or white crystalline powder. Smells strongly of ammonia.

Solubility: Freely soluble in water at room temperature.

AMMONIUM CHLORIDE. Sal-ammoniac. Chemical used in some toners, bleachers, sensitizers, etc.

Formula and molecular weight: NH_4Cl; 53·5.

Characteristics: White crystalline powder.

Solubility: Freely soluble in water at room temperature.

AMMONIUM DICHROMATE. Another name commonly used for ammonium bichromate.

AMMONIUM HYDROXIDE. Ammonia solution. Alkali used in certain developers, intensifiers and toners. Also in hypersensitizing.

Formula and molecular weight: NH_4OH; 35.

Characteristics: Colourless liquid with pungent smell. It is a solution of ammonia gas in water. The concentrated solution of sp. gr. 0·880, known as 0·880 ammonia, contains about 30 per cent by weight of ammonia gas.

AMMONIUM PERSULPHATE. Chemical used in some reducers.

Formula and molecular weight: $(NH_4)_2S_2O_8$; 228.

Characteristics: White crystalline powder. The solution does not keep.

Solubility: Highly soluble in water at room temperature.

AMMONIUM SULPHIDE. Used as a toner in the sulphide toning process and as a darkener for the bleached image in mercuric chloride intensification.

Formula and molecular weight: indefinite.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Characteristics: A yellow-brown solution with a most unpleasant smell.

AMMONIUM SULPHOCYANIDE. Ammonium rhodanate; ammonium thiocyanate. Used in gold toners and certain dye toners.

Formula and molecular weight: NH_4CNS; 76.

Characteristics: Very hygroscopic white crystals. Keep in stoppered bottles.

Solubility: Highly soluble in water at room temperature.

AMMONIUM THIOCYANATE. Another name for ammonium sulphocyanide. Used in gold toners.

AMMONIUM THIOSULPHATE. Used as a fixing salt in high-speed fixers.

Formula and molecular weight: $(NH_4)_2S_2O_3$; 148.

Characteristics: colourless crystalline salt.

Solubility: Freely soluble in water.

AMP. More commonly used abbreviation of ampere, which is the unit of volume of current or flow used in electricity.

AMPHITYPE. Name given by Sir John Herschel to his process (1844) by which either positive or negative pictures could be produced, according to manipulation. Fox Talbot gave the same name to an albumen-on-glass process which he patented in 1851. The pictures appeared either positive or negative, depending on the light in which they were viewed.

AMPLIFIER, IMAGE. Electronic system using an image converter tube to amplify or intensify a very faint image falling on a photocathode. The amplified image appears on a fluorescent screen or can be recorded on a photographic film.

See also: *Image amplifier.*

AMYL ACETATE. Solvent in certain film cements and negative varnishes.

Formula and molecular weight: $CH_3CO_2C_5H_{11}$; 130.

Characteristics: Colourless liquid with pear-drop-like smell. Very inflammable.

Solubility: Does not mix with water. Mixes with alcohol, acetone, etc., in all proportions.

ANAGLYPH. A method of stereoscopy invented by Louis Ducos de Hauron, 1891, and re-introduced as a novelty under different names several times since.

Two positives, forming a stereoscopic pair, are printed on one support, each in a different colour—generally blue-green and red. The observer looks at the picture through coloured glasses so that each eye looks through a glass of the complementary colour of the image it is to see.

If the right eye looks through a blue-green glass at the red image, that image will look black and the other will be invisible. Similarly the left eye will see the blue-green image and not see the red. In this way each eye sees a single image and the two impressions fuse to produce a stereoscopic sensation.

ANAMORPHOSCOPE. Cylindrical convex viewing mirror used for looking at distorted pictures of objects taken by photographing their reflections in a similar type of mirror. Seen normally, the pictures are meaningless; through the viewer they appear correct.

ANAMORPHOTIC LENS. Optical system in which image formation occurs on different scales in the vertical and horizontal directions. The system may consist either of cylindrical lenses or of prisms.

History. The first proposal for deliberately producing a regularly deformed optical image came from Sir David Brewster over a hundred years ago. He found it was possible to obtain achromatic deviation from two prisms made of the same material. In 1889 J. Anderton proposed the use of such a pair of prisms in front of a camera lens and in 1898 Dr. Rudolph proposed to replace one of Brewster's prisms by a double prism to achromatise the system. Of more recent years similar effects have been demonstrated by the use of either cylindrical lenses or mirrors. It is, however, only in the last fifteen years that anamorphotic systems have become something more than a novelty effect and have found a wide use in the motion picture field.

Taking and Projection. With the normal type of optical system the image produced is of the same geometry as the object viewed. With the anamorphotic lens system the geometry in one plane is "squeezed" or "unsqueezed" relative to the other plane. The usual arrangement is to

ANAMORPHIC SYSTEMS. A prism anamorphic attachment depends for its operation on the achromatized prisms which successively compress a parallel bundle of light rays (top). A cylindrical lens system (bottom) combines a positive cylindrical lens P and a negative one N to compress the light beam. The compression factor is the ratio D_1/D_2, in other words the width of the original beam divided by the width of the compressed beam. L is the taking or projection lens in front of which the anamorphic attachment is mounted.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

restore the geometry of the image either at the subsequent printing or projection stages.

Anamorphotic systems have not in themselves produced any startling change in the appearance of motion picture screen pictures. They are, however, a means of providing wide screen pictures of the panoramic type, whilst avoiding some of the practical difficulties which prevent conventional systems from providing an adequate standard of performance.

These difficulties are (1) that the extra screen width has to be provided by short focus projection lenses, leading to exaggerated image grain due to the greater optical magnification; and (2) that the projected picture has to be cropped top and bottom, with less light passing through this smaller aperture to illuminate the larger screen.

Anamorphotic projection systems largely overcome both problems. For example the largest area that can be projected by a standard projector has an aspect ratio of about $1\frac{1}{3}$: 1. If all this area is to be projected on to a screen having the Cinemascope aspect ratio of about $2\frac{1}{2}$ to 1 the optical projection magnification must be nearly twice as great horizontally as it is vertically. To maintain correct geometrical reproduction of the original scene, the image on the positive film must be unnaturally compressed so that its scale horizontally is half its scale vertically. Thus if the original object seen by the camera was a circle then the image on the positive film, achieved through an anamorphotic taking lens, must be an ellipse. This ellipse when projected on the screen via an anamorphotic projection attachment, will then appear once more as a circle.

Copying. Ancillary to the straightforward taking and projection through anamorphotic attachments, is the use of anamorphotic copying systems. This type of system can restore the normal geometry of a "squeezed" negative print on to the positive film stock for use in theatres having conventional 4 : 3 screen proportions. This sometimes entails both a reduction and an "unsqueezing" operation from the same anamorphotic copying lens. Such copying lenses employ a basic spherical system on either side of which are disposed cylindrical members. In one plane the cylindrical members have no power and the spherical member operates at a particular magnification whilst in the other plane the cylindrical members combine with the spherical member to achieve a different magnification. A development of this type of process has led to a picture quality improvement.

One wide-screen process utilizes the fact that positive film stock has less grain than negative film. The negative is obtained by normal taking lenses on larger than normal film stock (e.g. 65 mm. wide). At an anamorphotic printing stage the negative is reduced and a compression ratio introduced to produce a standard "squeezed" 35 mm. positive projection print.

In this process the use of normal lenses avoids light transmission and definition losses arising from bulky anamorphotic attachments. The reduction of the larger negative areas also takes a greater advantage of the finer grain of positive film stock. The angular fields covered are small at the printing stage and the copying system need only work at a fixed conjugate distance hence definition losses are reduced. Finally, one negative only need be used for the production of release prints compressed in any ratio to suit any screen aspect ratio or, alternatively for the production of normal release prints. P.A.M.

VARIABLE EXPANSION ATTACHMENT. The two prisms of an anamorphic system can be movable to give a variable compression or expansion. Swinging the prisms apart increases the compression, swinging them together decreases it.

ANASTIGMAT. A lens in which all optical defects, including astigmatism, have been corrected in its design. The first of this kind, the Protar lens, designed by Paul Rudolph, was introduced by Zeiss in 1889. All high class modern lenses are anastigmats.

ANDERSON, JAMES (born Isaac Atkinson), 1813–77. English photographer, originally a watercolour artist. Settled in Rome, 1838, and took the name of James Anderson. 1849, began taking photographs of antique sculpture and views of Rome. Later the firm of Anderson became known chiefly for reproductions of art in Italian museums; it continued until *c.* 1955.

ANDREE, SALOMON AUGUST, 1854–97. Swedish engineer and aeronaut. Perished in an attempt at crossing the North Pole by balloon in 1897. His photographic films were found in 1930 and developed to acceptable negatives, documenting the fate of the expedition.

ANDRESEN, MOMME, 1857–1951. German photographic scientist, later director of Agfa. Investigated and introducted new developing agents: para-phenylene-diamine in 1888; Eikonogen in 1889; para-aminophenol in 1891. Worked also on diazo printing. Wrote articles and books.

ANGERER, LUDWIG, 1827–79. Austrian professional photographer. Leading member

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

of the Wiener Photographische Gesellschaft (Photographic Society of Vienna). Famous for his Carte-de-Visite photographs and for his pictures (80 × 100 cm., without enlargement) taken with a Petzval-Voigtländer lens of 8 ins. diameter.

ANGLE OF VIEW. The angle of view of a lens is the angle subtended by the diagonal of the plate at the node of emergence of the lens. This is not necessarily the same as the angle of the lens, i.e., the angle that indicates the maximum covering capacity of the lens. In cameras fitted with one or more movements the lens must be able to cover more than the angle of view corresponding to the plate size.

See also: *Covering power.*

ANGLE SHOT. The orthodox way of photographing people or things is to point the camera at the subject from a viewpoint at eye level, with the back of the camera vertical and parallel to the principal plane of the subject—e.g., the front of a building. This approach avoids distortion of perspective and makes it easier to focus the important part of the subject.

When the camera is pointed at an angle to the subject, particularly from a close viewpoint, proportions tend to look distorted, parallel lines begin to converge more and more steeply, and it becomes more difficult to bring the whole depth of the subject into focus.

Sometimes distortion of perspective is introduced into photographs intentionally to achieve certain effects, but it is generally desirable to avoid it. This can be done either by holding the camera parallel to the plane which is to remain undistorted, or by using camera movements, as on technical cameras.

Pictorially, the extremes of angle shots are high and low angle shots.

A high angle shot is one taken from such a height that the subject is seen against the background of the ground itself or in which the horizon runs close to the top of the picture. Such a view tends to dwarf the subject and make it look top-heavy. This is because the vertical lines are foreshortened and the top of the subject, being much nearer to the camera than the bottom, looks so much bigger in proportion. In addition, the subject tends to become lost in a mass of surrounding detail of the same tone. High angle shots are only resorted to where the resulting distortion is sought deliberately—as in a portrait of a sitter with a heavy jaw which must be played down. They should not be used if the tones of the subject are much the same as those of its surroundings.

A low angle shot is one taken with the camera held as low as possible—generally with the photographer kneeling or even lying prone on the ground. Shooting from this angle has the advantage of showing the subject against a background either of the sky, or of objects so far away that they do not compete in tone with the subject itself and do not surround it with fussy detail. So a low angle simplifies the composition and isolates the subject.

Just as the high angle shot makes the subject look top heavy, the low angle shot emphasizes the width of the base. And by giving the subject a broad base and making the verticals taper towards the top of the picture, it imparts both stability and grace to the proportions. This treatment often improves pictures of tall slender buildings and of the human figure. But it is rarely a happy choice for portraiture because it makes the lower jaw and the fleshy part of the nose bulge unpleasantly. Where the lower part of the face needs emphasis, however, a low angle may be chosen deliberately.

Angle shots belong essentially to the field of the miniature because the small camera can be used at angles which would be practically impossible with a more cumbersome instrument. And when used at an extreme angle—e.g., looking up the front of a building—the miniature can still show everything in sharp focus from the brickwork a few feet away to the television aerial on the roof. This is possible because of the camera's short focal length lens, and the depth of field this allows. With a technical camera the same overall depth is achieved by the use of the tilting camera front. Even so, absolute sharpness is not always necessary or desirable for certain effects. F.P.

ANGSTROM (A). Unit that is now generally used to express the wavelength of light. There are 10 million Angstrom units to a millimetre. The visible spectrum extends from 7,000 Angstrom units (red light) to 4,000 Angstrom units (violet light).

See also: *Light.*

ANGULAR FIELD. Angle subtended at the lens by the largest object which the lens can image on the plate with acceptable sharpness.

See also: *Covering power.*

ANHYDROUS. Term indicating that a substance is free from water. In photography it distinguishes a chemical sold as a powder without water of crystallization from the same chemical in the hydrated form. When making up solutions it is important to use the anhydrous form of the chemical if that is specified since, weight for weight, it contains more of the active substance than its hydrates.

See also: *Chemical calculations.*

ANILINE PROCESS. Early line-printing process invented in 1865 in which a sheet of printing paper sensitized with ammonium-bichromate and phosphoric acid was developed by exposing it to the vapour of a suitable aniline dye.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

ANIMALS. Photographing native wild animals in their haunts is very much more difficult than, for instance, photographing birds at their nests. Birds have their eggs or young to form an irresistible bait, but animals as a rule keep their young well out of sight. And whereas most birds rely on their eyes and ears to warn them of the presence of the photographer, animals have keen noses which can often detect a watcher a hundred yards away.

Many of the very small creatures, like mice, voles, and shrews, remain hidden in the thick foliage that conceals their haunts. These are almost impossible to photograph in the wild state and must be captured and taken indoors.

Then again, many animals that do come out into the open do so only at night. These have to be photographed by flashlight.

There are, however, other animals that show themselves outside their lairs in daylight, particularly in the early morning and just before sunset. These may be photographed from a specially constructed hide erected down wind from the animals so that the photographer's scent is carried away.

Deer may pick up human scent at a hundred yards, so it is very difficult to get near enough to them to get a reasonable picture.

Bait. Foxes, badgers and rabbits can usually be induced to leave their lairs in daylight by tempting them with a suitable bait. This should be laid several days in advance near the entrance to the lair, and renewed regularly. At the same time as the first bait is laid, the hide should be set up so that the animals will become accustomed to it.

Foxes will come out of their holes for a bait of meat, or bread and milk; badgers like honey, jam or anything sweet; rabbits can be tempted with chopped parsley, and stoats and weasels will come out for fresh meat, particularly when they are feeding a litter.

The otter is a creature of regular habits, and it is possible to pick up his accustomed track and set the camera to cover it. Otters prefer to kill their food for themselves so they cannot be attracted by a bait, but as they show themselves on the bank and in the water by daylight, they can be photographed by waiting.

Equipment. The camera, tripod, and hide are similar to those used for bird photography. But because animals are more difficult to approach, the hide is generally farther away than for bird photography, and a long focus, or telephoto lens, should be used. Photographs can, however, be made with a normal angle lens if the camera is concealed near the lair and operated by some form of remote control.

Remote Exposure Control. Some photographers prefer to use remote control shutter release for dealing with wild subjects. This technique dispenses with the hide and calls for only a small amount of camouflage for the camera and its support.

Once the camera has been set up and focused on the bait or nest, or at the entrance to the lair, the photographer settles down some distance away to wait for the subject to make its appearance. If necessary he may use field glasses to tell him when the best picture offers itself. When that time comes, he simply fires the shutter by remote electrical or mechanical control.

The disadvantage of this method is that the photographer has to visit the camera after every exposure and also whenever changes in the light call for adjustment of the camera controls. Some cameras are designed to wind on the film and tension the shutter automatically after each exposure, but the noise of the camera mechanism is inclined to frighten the subjects, necessitating a waiting period, until they return to the scene. In a hide the photographer need not disburb the subject.

Automatic Exposure. There are several ways of making the subject take its own photograph while the photographer is away. One method of automatic shutter release is to get the animal to complete an electric circuit either by standing on a particular spot, breaking a thread stretched across its path, or seizing a bait.

This technique is uncertain in its results because it carries no guarantee that the subject will be in a suitable pose when the shutter clicks. And, as with remote exposure, the camera must be visited after every exposure.

But automatic exposure coupled with flash is very useful for securing pictures of nocturnal creatures which could not in any case be observed from a hide. In this way many striking photographs have been taken of subjects ranging from big game at a water hole to a fox robbing a hen run. The photographer can always be sure of getting a correctly exposed negative with the standardized light of the flash, but the success of exposures in daylight photographs depends upon the state of the lighting when the shutter clicks.

The most successful method of getting flying birds, flying mammals and insects, such as bats and butterflies, to "take their own photographs"

GLASS BOX SET-UP Small animals can be photographed in a glass-sided box containing suitable materials (earth, twigs, etc.) corresponding to natural surroundings. Removable glass partitions confine the animal to a limited distance zone from the camera and thus ensure overall sharpness.

CC-0. Jangamwadi Math Collection. Digitized by eGangotri Digital Preservation Foundation, Chandigarh

photographing the series, only the cels for the arms and for the legs would then be changed.

Thirdly, certain elements of a drawing may move as a whole, without being separately animated. Thus in a scene of a car travelling across the countryside, the car might be animated with a periodic movement sequence while the background slides past it behind (underneath on the cartoon bench). The background drawing in this case is made on a long strip which is moved across the field of view of the camera bit by bit between each successive frame. Such movement needs accurate calibration, and the cartoon bench may carry calibrated scales to help the cartoonist to shift a drawing through pre-determined distances.

Where animated drawings are split up into several layers of cels, the different parts of a drawing must of course register and match up exactly. The register pins on a cartoon desk (where the drawings are made) and on the baseboard of the camera ensure this. In more complex scenes several layers of cels may be animated independently of each other. Background and other features which move in their entirety are either not mounted on register pins, or are mounted on a second set of pins set in a block which slides in a groove along the cartoon bench.

Drawing Technique. For natural animation of diagrams, etc., it is sufficient to draw the various movement stages in a straightforward manner and photograph them in sequence. For cartooning, such movements tend, however, to appear jerky on the screen. This is partly because they lack the smoothness created by the slight blurring of images in a real motion picture, and partly because cartoons rely on exaggeration as well as simplification for their visual appeal. A strictly natural movement of a cartoon character would therefore appear subdued against the cartoon quality of the figures and other objects in the picture.

ANIMATING LINES. Top: If a line is animated to swing around the radius of a circle (left) the movement appears jerky. By distorting the lines (centre) we can animate an upward movement more smoothly; for a downward movement the lines would be distorted in the other direction (right). Bottom: The practical application of this is in animating a figure waving its arm up and down.

DISTORTION OF AREAS. When geometric shapes are animated to move, they must also be distorted for smooth motion. The distortion goes in the direction of the movement and is greater, the faster the speed. Right: If a shape moves along a complex path, all its lines are distorted to assume the course the object is following.

In cartoons this quality is emphasized by a variety of distortions in the movements portrayed. Thus straight lines moving at right angles to their length are drawn bent, curving away from the direction of the motion at the beginning of the movement. They bend in the opposite direction at the end. This conveys an exaggerated impression of inertia and so makes this inertia visible graphically on the film.

The same principle is applied to solid bodies. As a result such bodies appear squashed when they start to move, then unsquash and squash once more as they come to rest. The effect is that all objects seem to be endowed with an exaggerated elasticity. The degree of exaggeration is used to convey weight, speed of movement and inherent elasticity itself. Thus while in real life a cricket ball hit by a bat will hardly distort at all, a tennis ball (observable when filmed with a high speed cine camera) is noticeably squashed. In a cartoon the cricket ball is drawn visibly squashed, while a tennis ball is literally flattened at each impact.

Puppet Animation. While straightforward cartoons only involve the copying of a series of two-dimensional drawings, puppet films use three-dimensional sets in miniature. Some of the principles involved are the same, especially those relating to planning and timing the animation. Making a puppet film is, however, in many respects much more tricky since the illusion of perspective as well as movement must be conveyed in a tabletop set-up.

One practical problem is that of depth of field. The greater the scale of reproduction of any three-dimensional scene, the more restricted the depth of field becomes. For example a studio set of a room 15 feet wide may be recorded on a 16 mm. frame with a 500-fold reduction. A corresponding table-top scene 18 ins. wide only undergoes a 50-fold reduction. To obtain the same differential depth effect or

depth of field would require a lens aperture with ten times as high an *f* number.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Secondly, at close range the perspective effects are quite different. In particular it becomes necessary to create artificial perspectives by drawing them into the background and by making objects nearer the camera deliberately larger than similar objects farther away.

Thirdly, the animation itself calls for considerable skill since the limbs and other parts of the puppets must be moved by just the right amount between each frame. And while it is comparatively easy for someone who can draw to make a cartoon figure do almost anything, a puppet is limited by its physical capabilities such as joints, etc. Specialists in making professional puppet films sometimes employ highly complex and specially designed puppets with a very wide scope of movement. The head only of a puppet may be made in several dozen different versions to indicate varying facial expressions, these heads being interchanged on the body as required.

Animated Titles. Animation by single frame shooting can also produce a wide variety of trick title effects. These should still be planned frame by frame, but there is of course almost unlimited latitude since the timing does not have to conform to any nature-bound rules such as the rate of a human walk.

To make an animated title of for instance letters gradually falling into place, the individual letters are pushed one by one gradually into their required positions while the camera photographs frame after frame. Plastic or felt letters which can be rearranged at will indefinitely are most suitable for this purpose.

Alternatively a title may be drawn or painted step by step on its background, the camera exposing frame after frame as the title grows. Arrows on a map can be animated in the same way to show the progress of a journey.

If the map is required again subsequently, the arrow may be drawn or painted on a transparent plastic sheet and this placed over the map. It can then be extended exposure by exposure, so making the arrow appear to grow.

Animation of Still Pictures. With still transparencies the possibilities of animation are much more limited, since the successive presentation of different or partly different images is more complicated.

With slide projectors simple animation effects involving two transparencies are possible if two projectors are available. Each projector projects an image of its transparency on the screen, so that the image outlines that are not animated appear exactly superimposed. For the movement the light from the one projector is then faded out while the second projector fades in. This change-over should be fairly rapid and may be repeated to and fro to show simple periodic movements.

Another method, suitable for displaying transparencies, uses polarizing sheets. The stationary parts of the image to be animated are drawn or painted on an ordinary plastic sheet, and the alternative positions of portions to be animated laid on in the polarizing sheet material. This is orientated with its plane of polarization at right angles for the two positions. A further polarizing filter is placed in front of the light source and rotated. This makes the two polarizing areas on the image go light and dark alternately, producing the illusion of movement.

A similar system uses a bi-refringent plastic which is stuck over areas to be animated. On rotation of the polarizing filter in front of the light source these areas appear in fluctuating brightness. This method is suitable for creating the illusion of liquid flows, etc.

Yet another method of animating still pictures is image dissection. Here the subject (for example a diagram) is photographed through a lenticular screen which breaks up the image into strips with blank intervals between them. For the second image the lenticular screen is moved slightly at right angles to its line structure. Then the second image is recorded in the spaces between the lines belonging to the first image. For viewing, a similar lenticular screen is laid over the transparency (or even print) and slowly moved at right angles to the line pattern. This alternately brings the one and the other image into view. The line orientation should in this case be horizontal, otherwise an observer may see one image with one eye and the other image with the other eye, as in a parallax stereogram. By suitable choice of the lenticular screen it may be possible to get several different or partly different images on one picture. L.A.M.

ANNAN, JAMES CRAIG, 1864–1946. Scottish photographer. Son of Thomas Annan, whose portrait studio in Glasgow he took over. Introduced the photogravure process of Karl Klič into Britain, 1883. Leading pictorialist and member of the Linked Ring; first president of the International Society of Pictorial Photographers. Propagated the work of D. O. Hill and R. Adamson *c.* 1900 in exhibitions and by issuing a small selection of photogravures.

ANNAN, THOMAS, 1829–87. Scottish portrait photographer. Father of James Craig Annan, friend of D. O. Hill and of Sir J. W. Swan. Made (1879–81) carbon prints of Hill's calotypes, and introduced Swan's carbon process in Scotland. He photographed Hill's painting of the signing of the Deed of Demission at Edinburgh with a specially built camera (14 × 32 ins.). Made carbon prints as large as 21¼ × 48 ins.

CC-0. Agrasen Digital Preservation Foundation, Chandigarh

ANSCHÜTZ, OTTOMAR, 1846–1907. German photographer. 1882 began taking instantaneous serial pictures of animals in motion using a hand camera fitted with a focal plane shutter. Devised electrical rapid viewing instrument for stroboscopic synthesis of these pictures (Electrotachyscope) 1887—one of the forerunners of cinematography.

ANTHONY, EDWARD, 1818–88. American engineer. Became one of the early daguerreotypists and made a photographic survey of parts of the U.S./Canadian boundary. Set up in business as a photographer in 1842, later became one of the largest photographic dealers. He founded *Anthony's Bulletin of Photography*. The firm of E. & H. T. Anthony & Co. combined in 1901 with Scovill & Adams Co. to form the Anthony & Scovill Co. which in 1907 became Ansco Co. and in 1928 Agfa Ansco Co. Biography by American Museum of Photography (New York, 1942).

ANTI-FOGGING AGENT. Chemical included in a developer to retard the formation of development fog. The oldest known anti-fogging agent is potassium bromide; nowadays a variety of organic substances have been found more effective and more selective.

See also: *Developer improver.*

ANTI-HALATION BACKING. Most modern negative materials have some form of anti-halation backing to absorb the light that passes through the emulsion. If the light is not absorbed, some of it is reflected and falls on the under side of the emulsion layer, causing halation.

There are several forms of halation backing: a coat of dye or pigment painted on dyed gelatin; an intermediate layer of dyed gelatin between the emulsion and the support; and a dye that is incorporated in the base of the material itself.

Dyes or pigments may be applied directly to the back of the support. Red or purple dyes are used for orthochromatic, and blue-green for panchromatic, materials. The dye in each case absorbs those wavelengths of light to which the emulsion is most sensitive.

This type of anti-halation backing is commonly used for glass plates. The backing dye or pigment is generally mixed with gum, which make it adhere when dry, but allows it to dissolve away during processing.

A backing layer is a gelatin layer incorporating the dye and is applied to the back of the support. This type of anti-halation backing is almost always used on roll and sheet films, because the gelatin layer counteracts the tendency of the emulsion layer to make the film curl. The backing layer remains on the film all the time, but the dyes bleach out during processing.

Reversal and colour films frequently have an intermediate anti-halo layer, applied between the emulsion (or emulsions) and their support. This layer contains colloidal silver and is the most effective single anti-halation protection. This is because any light reflected from the back of the support has to pass through the layer twice: once before, and once after reflection.

Since reversal processing and colour processing procedures involve a silver bleaching stage, the colloidal silver automatically disappears during processing, leaving the layer clear. For this reason black-and-white reversal films are not suitable for processing to a negative. An intermediate layer of this kind does not by itself provide any counteraction to the curl of the film.

The film base of many 35 mm. films is itself dyed with a blue-grey or neutral-grey dye which acts in the same way as an intermediate layer, i.e., any light that passes through the emulsion is filtered both before and after it is reflected from the back of the support.

The dye used is not removed in processing, but it does not interfere with printing.

Several modern 35 mm. films carry an anti-halo backing, similar to roll films, in addition to the dyed film base.

ANTINOUS RELEASE. Originally a proprietary name, now commonly applied to all flexible wire or cable types of shutter release.

ANTIQUES. The photography of museum and collector's pieces needs considerable technical skill. The aim is usually to produce a factual presentation of the object, from which the connoisseur could get much of the information he would expect to obtain by a visual examination of the object itself. It must be to scale, free from distortion, indicate surface texture and show all decipherable detail.

Equipment. To do this sort of work properly a rear-focusing field camera is essential. It must have an extension more than twice the focal length of the normal camera lens, the length of this being at least equal to the diagonal of the film or plate it has to cover. focal length of the lens employed and the focal length of the lens should be at least equal to the diagonal of the film or plate it has to cover. Back focusing is necessary for working to scale, as otherwise any movement of the lens backwards or forwards in focusing changes the distance between the lens and the object and thus alters the size of the image.

The usual practice when photographing a number of articles to the same scale (snuff boxes, coins, miniatures and the like) is to set the camera by focusing on a foot rule and measuring the image on the focusing screen. It is then only necessary to move the camera

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

backwards and forwards until the object is sharp on the focusing screen.

A double extension camera is necessary because so often in this work the object must be reproduced same-size and to do this the camera must be extended to twice the focal length of the lens in use.

A swing back is absolutely essential as converging verticals are no more permissible in a photograph of, say, a cabinet, than they are in a photograph of a building. This statement applies equally to converging horizontals, which should also be corrected by use of the relevant camera movements.

The equipment should include at least three lenses—normal, long-focus, and wide angle—to meet all possible needs. These lenses should of course be of the highest possible quality.

Lighting. No hard and fast rules can be laid down on the lighting of antiques, as such objects are extremely varied. Some require soft diffused light; with others even spotlights might be suitably brought into play.

As exposure time is seldom important, it is always a good plan to use a smaller stop than would normally give the depth of field necessary to cover the subject. Extreme stopping down can, however, lead to an ultimate loss of quality, caused by diffraction. The correct use of tilt of the lens panel, on a camera where such movement is possible, can achieve overall sharpness without extensive stopping down.

In this class of work it is essential to expose for the shadows; modern slow emulsions have enough latitude to look after the highlight detail if development is not carried too far.

The background needs to be carefully chosen to give a clear contrast with the outline of the subject on both lighted and shadow sides. It should be coloured or lighted to come out on the print as a neutral grey; it should never be white, as the strong reflected light tends to be spread by halation and destroy the crisp definition around the edges of the subject.

Sensitized Material. Many experienced technical photographers prefer to use sheet film or possibly plates, as these can be processed individually. When using roll-film it is important, on any one roll of film, to shoot only similar subjects under similar lighting conditions, so that processing can be suited to the entire roll. Any work such as blocking out or titling that may have to be carried out on the negative is easier on a large sheet film or plate than on a comparatively small piece of roll-film. Whether panchromatic or ordinary colour-blind emulsions are used will depend on the subject.

Ordinary colour-blind emulsions are preferable when statuary or the like has to be reproduced in its natural grey tones, but, for subjects containing colour, a panchromatic emulsion with a suitable filter is essential. The slower emulsions, whether panchromatic or ordinary, are preferable unless the subject has to be photographed *in situ* in poor light.

Difficult out of twenty subjects will be suitably corrected on pan plates by using a 3× yellow filter but, very occasionally in antiques, one gets rich colours in, say, rosewood or marquetry or the tortoiseshell inlay on Buhl furniture which call for an orange filter. Focusing should always be done with the filter in position because the filter may cause a slight shift in the focus of the rays that form the photographic image.

Processing. In many branches of photography, processing which gives approximately correct tone values is all that is required. This standard is not good enough for a negative which may at any moment be the only record of a unique piece which has met with disaster. For that reason the normal practice of taking a spool of mixed subjects at varying exposures and developing it by time and temperature in a standard developer will not do. Such important records must be developed separately to a gradation and contrast scale which is complementary to that of the subject and yet may vary from one subject to the next.

Photographers who specialize in this critical work often develop by inspection. The developer employed is almost invariably a standard pyro-soda formula. With this it is possible to pre-determine the character of a negative by varying the pyro content; a solution rich in pyro will tend to produce a contrasty negative, whereas by reducing the concentration the same exposed material can be made to yield the softest image it is possible to print.

Photographs of antiques are mostly used for records and for catalogue reproduction, and for that reason they should preferably be printed on glossy or smooth paper which gives the maximum resolution and rendering of detail. C.D.(V.G.)

ANTI-REFLECTION COATING. Very thin coating of a metallic fluoride applied to a glass surface—e.g., of a lens—to reduce light lost by reflection.

See also: *Coated lens.*

ANTI-SCREEN PLATES. Commercially used term for plates whose blue sensitivity has been reduced by dyes. Such plates may be used without a colour filter to produce effects normally obtained with an orthochromatic plate and a yellow filter.

APERTURE. Size of the lens opening through which the light passes. There are several definitions of aperture, according to the exact parameter referred to by the term. Some of these are specified in the British Standard BS. 1019: 1963.

Limiting Aperture. This is the physical limit—for example the iris diaphragm or the lens

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

mount itself—to a light beam from an object point at the lens axis. If the lens has an iris diaphragm, the limiting aperture at any setting is the actual diameter of the diaphragm opening.

Effective Aperture. This is the diameter of the light beam reaching the lens from a distant object point along its axis, which passes through the edge of the limiting aperture. The object here is assumed to be at an infinite distance, so that the light beam can be assumed to be parallel. The physical stop diameter (limiting aperture) can be larger or smaller than the effective aperture, depending on the lens construction. It is however the effective aperture that determines the light passing power of the lens.

The effective aperture is a diameter; if the limiting aperture is not a circle, the size of the effective aperture is specified by the diameter of a circle of equal area.

Relative Aperture. This is the ratio of the focal length of the lens to the diameter of the effective aperture. For example if a lens has a focal length of 100 mm. and the effective aperture has a diameter of 25 mm., the relative aperture is $100/25 = 4$. This is also known as the *f*-number, and is expressed as f/4, *f*4, 1 : 4, etc.

The light passing power of the lens, and hence the exposure required in a photograph, depends on the relative aperture. Lenses of different focal length and different effective apertures still form an image of the same brightness, other things being equal, if the relative aperture or *f*-number is the same. (In practice light losses in the lens by absorption and reflection complicate the situation slightly.) In common photographic parlance the term aperture is taken to mean the relative aperture.

The light transmitted through the lens is proportional to the area of the effective aperture, and hence inversely proportional to the square of the relative aperture of *f*-number. In other words a lens set to *f* 4 passes four times the light of a lens set to *f* 8.

Aperture Ratio. When the light beam going through the lens comes from a nearer object, and hence is no longer parallel, the light passing power depends on the aperture ratio. This is the value of $2n \sin \alpha$, where n is the refractive index of the medium in the image space (practically 1 with air) and α is the angle measured in the same medium, between the axis and a ray from the axial object point which passes through the edge of the limiting aperture.

When the object is at infinity, the aperture ratio with a medium of a refractive index of 1 is equal to the relative aperture. With objects at nearer distances the aperture ratio can be taken as the image distance divided by the effective aperture at the infinity setting. For example when a lens of relative aperture *f* 4 is used for same-size copying, the lens-to-image distance is twice the focal length. The aperture ratio then becomes 1 : 8.

The exposure for a photograph taken under these conditions must be increased in proportion to the square of the aperture ratio divided by the relative aperture—in other words $(8/4)^2 =$ 4 times the exposure with the lens set to infinity. In practice it is inconvenient to work out aperture ratios for different distance settings, and a simple value for the exposure factor is $(M + 1)^2$, where M is the magnification (image size/object size). Where the magnification is less than 0·1, the exposure factor is small enough to be negligible in practice.

Numerical Aperture. This is a parameter used to express the light gathering power as well as the angle of view of microscope objectives. The numerical aperture (N.A.) is the sine of half the angle of view of the objective, multiplied by the refractive index of the medium in which the objective is used (air, oil, etc.).

See also: *Diaphragm; Depth of field; Exposure; Exposure automation; Lens; Optical calculations; Photomicrography.*

APEX SYSTEM. Abbreviated term for *A*ddi-tive system of *P*hotographic *E*xposure. This is based on a logarithmic way of expressing the camera exposure equation:

$$A_v + T_v = B_v + S_v = E_v$$

where $A_v = \text{Log}_2 f^2$ (*f* being the lens aperture); $T_v = \text{Log}_2 1/T$ (T being the exposure time in seconds); $B_v = \text{Log}_2 B/6$ (B being the lighting level in foot-candles); $S_v = \text{Log}_2 kS$ (S being the arithmetic film speed and k a constant); E_v = exposure value.

This form of expression of the camera exposure equation is of interest in connection with the exposure value scale marked on many modern camera shutters, and also in connection with the ASA and BSI logarithmic speed figures adopted in the corresponding standards since 1960. The logarithmic speeds correspond directly to values for S_v.

The terms in the above equation all carry whole-number integers, and are thus easy to manipulate mathematically. These terms are also known as unit values, and some cameras even carry such unit values for their aperture and shutter speed settings. Adding together the unit value for the lens aperture and the unit value for the shutter speed thus gives the exposure value, and there is a wide range of possible combinations of aperture unit value and time unit value to correspond to the same exposure value. (This disregards for the moment the effect of reciprocity failure.)

Further, if the unit value for the lighting (B_v in the above equation) is known or can be determined from an instrument, it is only necessary to add it to the logarithmic film speed value to get the required exposure setting on the camera. The use of the logarithmic scale to the base 2 means that every increase of one step in any of the unit values corresponds to a halving of the exposure, in the same way as with the exposure value scale.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

UNIT VALUES COMPARED

Unit Value	Corresponds to Aperture	Exposure Time (sec.)	Lighting Level (ft. candles*)	Film Speed A.S.A. Log	and B.S.I. Arith.
0	f 1	1	12 (0·35)	0°	3
1	f 1·4	1/2	25 (0·70)	1°	6
2	f 2	1/4	50 (1·41)	2°	12
3	f 2·8	1/8	100 (2·82)	3°	25
4	f 4	1/15	200 (5·63)	4°	50
5	f 5·6	1/30	400 (11·3)	5°	100
6	f 8	1/60	800 (22·5)	6°	200
7	f 11	1/125	1,600 (45·1)	7°	400
8	f 16	1/250	3,200 (90·1)	8°	800
9	f 22	1/500	6,400 (180)	9°	1,600
10	f 32	1/1000	13,000 (360)	10°	3,200
11	f 45	1/2000	26,000 (721)	11°	6,400

* Candle as per square foot given in brackets.

Owing to the suitability of the ASA log (to the base 2) speed values, the latter are often—though incorrectly—referred to as APEX speeds.

APLANAT. Lens corrected to give an image as free as possible from chromatic and spherical aberration. The first true aplanat was introduced by Karl August von Steinheil in 1866.

APOCHROMAT. Lens (usually microscope object glass or special process lens), which has been corrected for the three primary spectral colours as opposed to achromatic lenses which are corrected for two colours only.

APRON. Long celluloid or plastic band with dimpled edges in contact with which the film is wrapped around the reel of one type of 35 mm. developing tank. Used in some roll film tanks.

An apron is also the endless fabric band used on rotary glazers.

See also: *Glazers and glazing machines; Tanks.*

AQUARIA. Both black-and-white and colour photographs may be taken of fish and other aquatic life in tanks in private or public aquariums. Successful pictures can be made both by natural or artificial lighting.

See also: *Fish.*

AQUATINT. Another name for the gum bichromate process following a fine art term for a form of etching.

ARABIC GUM. Form of gum used in the Arabin or gum bichromate process. It is more usually called gum arabic.

See also: *Gum arabic.*

ARABIN PROCESS. Another name for the gum-bichromate process perfected by Nelson K. Cherril who published an account of it in June, 1909.

ARAGO, FRANÇOIS, 1786–1853. French astronomer, physicist and politician. Used his influence in 1839 to obtain official recognition for the daguerreotype, and Government pensions for Daguerre and Isidore Niépce. Made the first official announcement of the daguerreotype, 7th January, 1839, and made the process public, 19th August, 1839, at a joint session of the French Academies of the Sciences and Fine Arts. Biographies by Lunel (1853), and Audigamme: *Arago, son genie et son influence* (1869).

ARC. Electric discharge across a gap in a circuit. The arc may be struck between carbons, as in the arc lamp, when it provides an intense concentrated source of light; or between electrodes in a gas-filled bulb or tube, as in the discharge tube, and electronic flash tubes. In the form of an intermittent spark the arc may provide illumination for high-speed cinematography.

The term is also used to indicate sparking on faulty contacts.

ARCHAEOLOGY

As scientific methods are now applied to archaeological work, photography has come to be a vital part of every excavation. It falls roughly into three categories: aerial photography, field work and indoor work.

What is needed in every case is a clear, sharp picture. The photographer cannot choose his composition; his job is to present the truth, and this requirement governs his choice of equipment, preparation and lighting. And he must be prepared to tackle a great variety of subjects. Archaeological photographs may be required to reveal the details of walls, floors, foundations, hearths, post holes, doorways, mosaic pavements, or small finds *in situ*, or they may have to record changes of colour or texture of the soil in a vertical of horizontal plane, denoting layers of occupation, foundation, trenches, etc. The newcomer to archaeological photography will find it helpful to study the illustrations in books and periodicals devoted to this exacting branch of photography.

AERIAL PHOTOGRAPHY

Aerial photographs have been used for a long time by archaeologists to help them in their study of the remains of ancient civilizations. The camera from the air can show the layout of a camp, a village, or a city, in a picture that would otherwise have called for a tedious and expensive ground survey.

CC-0. Agamnuam Digital Preservation Foundation Chandigarh

The more general study of the face of the earth, known as geomorphology, also makes frequent use of aerial photography.

More recently observers have noticed that from time to time patterns appeared in aerial photographs that could not at first be seen on the ground. Research on the site confirmed that the markings indicated the presence of the buried ruins of ancient streets and houses. From then on, it showed that many otherwise invisible sites could be rendered clearly on photographs taken from about 5,000 feet in the very early morning or late evening. The extremely oblique rays of the sun at such times throw up shallow relief that could not otherwise be seen.

Even where there is no relief at all, vanished sites are often revealed by variations in the colour of crops growing on the land. These differences are more marked at some growing seasons than others. Colour differences can sometimes be traced to the stronger initial growth of crops over silted-up ditches which in dry seasons retain more moisture than the surrounding earth.

It is an interesting fact that no matter how often or for how many years the land has been ploughed and re-ploughed over such sites, it is impossible to obliterate all traces. Even when the visible surface signs have disappeared, aerial photography, if necessary with special—e.g., infra-red—sensitive materials and filters, can make them appear again.

Method. There are two types of photography:

(1) The vertical pin-point of a selected site. This has the overwhelming advantage of giving a definite scale to the photograph when the height from ground, focal length of lens, and width of negative are known. A number of such vertical shots may also be taken in the form of a vertical line overlap or even a mosaic.

(2) The oblique photograph taken from the side of the aircraft (either port or starboard). This is more of a picture and is taken at a lower level than the vertical type. It is easier to photograph this way, but the working out of a true scale is a highly complicated mathematical procedure. For a vertical photograph the fore and aft line of the aircraft and wing levels must be truly horizontal to the ground, and the camera must be suspended in the aircraft in such a manner as to avoid or lessen vibration. When taking oblique shots, the operator and his camera must not be in contact with the side of the aircraft at the moment of exposure or camera shake may be produced.

The work calls for close co-operation between pilot and photographer. Before the flight, contours and other information about the area are studied with the aid of maps and the timing and lines of flight are decided on.

There is always one type of lighting that gives the most information according to the relief of the subject and the state of the vegetation.

Oblique shots are generally best taken from a height of not more than 500 feet, in order not to lose the height of the subjects like cairns or burial mounds and to get the subject as large as possible on the negative.

Vertical pin-points require extreme care to get the subject in the centre of the negative; where possible it is better to make a series of pictures, each with a 60 per cent forward overlap. This method also allows any two of the pictures to be observed stereoscopically (a process known as interpretation). At the magnification given by the stereoscope, all the contours and details in the photograph are revealed.

Subjects in very low relief call for rising or setting sun and good results will often be obtained, particularly in the Middle or Far East, by flying into the sun.

Spring and autumn are very good seasons to photograph and show individual characteristics, because immediately over buried stone and brick walls the earth provides less moisture and the crops do not grow quite so thickly as in the earth surrounding the walls. The ripening and yellowing of the two occur at different times and the difference in colour can be distinguished by a panchromatic emulsion. The reverse happens with ditches or hut circles, because the ditch or hut marking, no matter how often ploughed, always provides a greater depth of good soil; this holds more water than the adjacent ground and provides a more lush growth of crop.

While the work is better carried out by two people with good ground work first, it can be done in a small light aircraft or even helicopter by a good pilot, using remote camera control.

Equipment. Costly equipment is not necessary for a survey. A good quarter plate or $2\frac{1}{2} \times 3\frac{1}{2}$ ins. film camera, with a first-class anastigmat lens and speeded shutter, fitted with a pale yellow or a pale green filter, and loaded with a fine grain material, is satisfactory for normal work. The shots must be made through the open window with the bellows of the camera protected against the airstream. If the windows cannot be opened, there must be no reflections from lights inside the cabin.

Where possible, the photographs are taken from an aeroplane, but archaeological expeditions also use balloons and kites. These are suitable for comparatively small areas and for taking photographs up to about 150 feet. The balloon or kite is flown over the site and the camera shutter is released by a simple time-switch.

Both oblique and vertical photographs are used, each type having special advantages.

The sensitive material normally used in this and other kinds of aerial photography is the ordinary aero film. This is simply a standard panchromatic material with high contrast, developing with normal technique to about gamma 1·5.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Prints from aerial negatives should be on the soft side to retain the maximum shadow detail.

In addition to black-and-white pictures, much useful work is nowadays done on colour film. Often details which give no visible contrast on black-and-white material show up clearly as a colour difference on colour film. Infra-red also offers possibilities. G.T.S. & M.B.C.

GROUND PHOTOGRAPHY

Before commencing work in the field or indoors, much time must be spent preparing the ground, whether the photographs are to accompany a report or merely for the records. In order to bring out the details—by which some historical point may later be illustrated—every subject needs careful preparation. In the case of trenches, the edges must be sharp and straight, the dump kept at least two feet from the edge and the intervening space swept with a hard brush. Floors must be swept to remove all loose earth and until the surface looks clean and hard; stones must be thoroughly brushed, and mosaic pavements should be washed. The cleaning is generally the joint responsibility of the photographer and the site supervisor.

It may be desirable to obtain a comprehensive view of a complicated site from a high staging or an extension ladder. Under such conditions the photographer may have to work under conditions of some difficulty being restricted by the size of the platform available.

Cameras. The choice of a camera may be governed by personal taste, or the finances of the excavation, but since the object is sharpness and detail in the photographs, the equipment should if possible include a field camera, with focusing screen, or a twin-lens reflex. The photographer must be able to see exactly what he is getting into his picture and this cannot be done adequately with a viewfinder.

A whole-plate or half-plate field camera has an enormous advantage over the miniature and folding cameras in having all the camera movements so necessary in this kind of work; rising front, swing back, cross front and double or triple extension. For work in a restricted space, such as a narrow trench or a tomb, a 9 × 12 cm. or quarter-plate camera is ideal; it has most of the movements of the larger makes and the negatives are big enough to do away with the need for enlarging, except for reproduction in publications.

Full recording involves taking a great number of photographs; this is specially true of foreign excavations, when many, if not all, of the finds have to be left in the country, and will not be available at a later date. Only a selection of these photographs will be used for publication in the final report, but the rest are an essential part of the records. They must provide a detailed record of every stage of the excavation. As all 35 mm. negatives have to be enlarged, while from the larger camera a contact print is all that is necessary, the larger camera actually saves much time and expense.

Where running costs have to be kept down, the miniature and twin-lens reflex cameras cost less for sensitive materials than the field camera, and the darkroom requirements will be correspondingly modest. But even if a miniature camera must be chosen, it is advisable to buy one with a focusing screen and interchangeable lenses—i.e., a miniature reflex. A camera of this type is very useful on any excavation both for photographing small finds and for making colour transparencies. Transparencies are used very sparingly, if at all, for illustrating reports because of the cost of colour reproduction, but they are particularly useful for lantern lectures.

Lens. It is not necessary for the lens to work at a wide aperture; the archaeological photographer, whose subjects do not move, seldom requires anything larger than *f* 8. However, he does need at least two lenses, one of medium focal length, and one of short focal length (wide angle), with, if possible, a third of long focal length. The wide-angle lens is essential when there are architectural remains on the site. A telephoto lens can be very useful on occasions, but it is an expensive extra and by no means necessary in normal archaeological work.

Tripod. The tripod should be very rigid, have a tilting head for vertical work, and be adjustable in height to at least six feet. A small tripod with a ball joint head is a necessity for work in restricted areas. It should be as simple to adjust as possible, especially for work in tombs, where there is little freedom of movement.

Exposure Meter. A good photo-electric exposure meter is a necessary part of the equipment, but it will not always be possible to get an accurate reading for the whole subject. When photographing a deep trench and in similar instances where the light strikes unevenly, the reading for the one part will be necessarily much higher than for the other. In such cases the reading should be taken for the darkest shadow; the over-exposed highlight areas of the negative can be corrected in the printing.

Scales. An archaeological photograph which does not include some sort of scale is quite meaningless. Surveying rods are generally used and when they are shown vertically they should always be parallel with the sides of the focusing screen or viewfinder. When used horizontally it is frequently better to lay them along the bottom of a wall or structure of some sort, than to have them parallel to the base of the picture.

For less extensive views a smaller scale should be used and in every case the scales should be clearly marked and kept repainted. They should not be so large and clumsy that they take away attention from the subject; they should be carefully placed where they will give scale to the subject, but not where, by their size and position, they form a major distrac-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

SCALE: Top left: *A record shot by itself gives little idea of size.* Top right: *A surveyor's 6 feet scale rod against the base of the object will provide a comparison.* Bottom left: *In oblique views the scale rod may be parallel to the base of the pictures.* Bottom right: *If parallel to the base of the object the divisions help to indicate actual depth of the subject.*

tion. For small finds, groups of pottery, etc., cardboard scales of varying sizes can be cut and painted to show alternate black and white divisions.

Filters. Filters are useful in archaeological work for emphasizing changes of colour in stratification and bringing out the colour and texture of pottery and the colour of mosaics. A set of tri-colour red, tri-colour green, light yellow or light green is all that will be needed. For special filters, the necessary increase of exposure is always given on a printed slip included with the filters as supplied by the makers.

Additional Equipment. Other items of necessary equipment are a small spirit level, a plumb line and a lens hood. The photographer will always find it useful to have with him one or two small decorator's paint brushes for last-minute brushing, drawing pins, plasticine and a set of small tools.

Negative Materials. Panchromatic materials are the most satisfactory for general use, though there are occasions when it is useful to have a supply of ortho as well. The speed and make of film is a matter of choice, but it is better to sacrifice speed for fine grain qualities where the negatives will have to be enlarged later. Developers made up in packets are preferable because they can be readily mixed in even the most primitive conditions in the field. It is also advisable to use tanks for processing because they save time, keep out the dust and obviate finger marks and other evils.

If miniature or roll film cameras are to be used, the films should be processed in daylight developing tanks. A changing bag can be used for loading them into the tank, thus doing away with the necessity for a darkroom. The printing is best done when the expedition returns to base.

Lighting. With archaeological subjects, the right lighting is of the utmost importance and from the beginning of the excavation the photographer must study the conditions on the site at all hours of the day and make notes for future reference. For most work in eastern countries at least it is advisable to avoid full sunlight. A photograph of a long trench is not improved by having the upper part in strong sunlight and the lower levels in deep shadow, and a collection of large storage jars photographed *in situ* in brilliant sunshine is confusing and unsatisfactory. For such photographs, sun obscured by light cloud is ideal. As this cannot often be arranged, the best times are early morning and just after sunset.

The viewpoint will usually have been chosen by the director of the excavation, and the photographer and site supervisor must co-operate in seeing that everything is ready and no time is lost in last-minute tidying up and arranging the gear. The position of the camera and ranging rods should always be tried out beforehand. The light at the foot of a deep trench or in a dark corner can often be improved by the use of large sheets of white cardboard or mirrors as reflectors.

Subjects such as inscriptions, objects with a raised pattern and decorated masonry are better not taken in the middle of the day, but when the sun strikes them obliquely; some are best taken with the sun directly behind them with the lens carefully shaded against the direct rays.

In photographing small finds and potsherds vertically, if the subject rests on a square of ground glass supported across two boxes, with

TRENCHES. Top: *Deeper parts of trenches and excavations rarely receive sufficient direct light, resulting in excessive contrast and lack of detail in the shadow areas.* Bottom: *A reflector or mirror will throw additional light into the shadows.*

LIGHTING RELIEFS. Right: *Engraved inscriptions etc., need side lighting to make them stand out.* Left: *Front light illuminates the surface evenly without casting shadows. It therefore fails to bring out any relief in the subject.*

a sheet of white paper underneath, there will be no confusing or featureless shadows.

Photographing tombs and confined spaces where there is little or no light presents many difficulties; flash is quick and convenient, but tends to give hard shadows. If a portable generator is available, a very satisfactory type of diffused light is obtained by throwing the beam on to the ceiling or walls. (This can also be achieved by "bouncing" flash off the same surfaces.) However, in many cases there is so little room to work that there might not be space for the necessary electrical apparatus. A makeshift can be improvised with car head lamps at the end of a long flex, but the ideal is a proper adjustable lighting stand.

Indoor Work. In photographing specimens indoors, the technique does not differ basically from ordinary studio work. In the field, however, the light may not be under the control of the photographer, but good results can be obtained by natural daylight if sheets of white cardboard are used to light the side of a subject farthest from the light coming through a window or door. Large sheets of drawing paper will serve as a background and these must be continually renewed as they become creased or soiled. The pottery is normally washed before it reaches the photographer; it may, however, need a final brush and in some cases a pattern can be emphasized if the pottery is damped with a wet brush. Plasticine lightly rubbed over troublesome highlights on glazed or shiny objects will help to tone them down.

Filing System. A reliable system of filing is essential so that the director, even after a lapse of years, will be able to find a particular photograph without searching through hundreds. The method usually adopted is to number the negatives on the clear edge with Indian ink, prefacing the number with the name of the site. The number is written on the outside of the negative envelope, and a record made of the date, viewpoint, time of day, lighting, make and speed of film and exposure. These details are entered in a negative register and copied on to the back of the record print. N.L.

Book: *Photography for Archaeologists*, by M. B. Cookson (London).

ARCHER, FREDERICK SCOTT, 1813–57. English professional photographer and sculptor. Inventor of the wet collodion process on glass plates, which he presented as a free gift to the world, March 1851. This first practicable photographic process not patented in Britain superseded the daguerreotype and Calotype and was used by photographers for thirty years. False claimants tried to rob Archer of the honour as inventor. After Talbot's claim that the process was covered by his Calotype patent was refuted by law in December 1854, photography for the first time became widespread and fortunes were made, yet Archer died in extreme poverty. He also devised, in collaboration with Peter W. Fry, the Ambrotype process, or collodion positive on glass, and invented the stripping of collodion films, since applied in much photomechanical work. Archer was also author of the first manual on collodion photography.

ARC (HIGH INTENSITY). Type of arc used in some arc lamps. With low intensity A.C. arcs, certain drawbacks prevent their use in cinematography where a steady point-source light is required. By employing carbons run at a sufficiently high current density, a relatively flickerless and compact source of illumination is obtained which is suitable for projection.

ARCHITECTURE

An architectural photograph might show an entire building, a section of a building, either interior or exterior, or some detail of a building in close-up. Architectural photography is used for scientific purposes, for reproduction either in the form of picture postcards or in magazines, for advertising, or for the records of builders and architects. For the latter purpose photographs are normally taken at regular intervals from specific points of view, following through the stages of development to the completion of a project. Architectural photography can, of course, be applied in numerous other ways.

Records. Accurate records, e.g., of historic buildings such as those made for the National Buildings Record, are best taken under strictly controlled conditions, among them being that the camera should have a rigid body, be set absolutely square and level and record the whole building in a series of views, each of

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

which shows two sides and an indication of one of the other camera stations. Preferably each picture should include a measuring rod in contact with one of the main walls. Such work is outside the scope of the ordinary photographer unless he works in co-operation with the National Buildings Record.

Pictorial Studies. Buildings are excellent subjects for the pictorial photographer in so far as they exhibit beauty of proportion and texture, and in the way they lend themselves to bold effects of light and shade. The pictorial worker might approach the subject as a means of personal expression; he may deliberately introduce distortion with angle shots, or suppress detail by using soft focus, or give extra emphasis to certain features when composing.

In creating a pictorial study of a piece of architecture, the photographer may include one or more of the surrounding features, or more or less of the background. He can control the importance of such items by varying his viewpoint and distance to alter the angle or perspective. Foliage forms one of the most useful aids of this kind; often the inclusion of adjacent trees introduces a balancing element to the composition or provides a useful contrast for the hard outlines of the building. A wide angle lens and a close viewpoint can achieve deliberately exaggerated perspective effects.

Normal Photographs. Outside these specialized fields, architectural photography is simply concerned with producing a reasonably good likeness of the building which will convey a truthful impression of its shape and proportions. As a rule, the surroundings, too, are important, contributing to the distinctive character of the building.

Architectural Styles. It is useful for the photographer of architecture to have some knowledge of the various architectural styles, even if his interest goes no further than the surface. Each period has its own pictorial features and the photographer who can recognize them knows what to expect from the guide book classification of any particular building. So he can tell in advance which places will yield the type of picture that interests him most.

The principal guide book classifications of English ecclesiastical and domestic architecture are Norman (1050–1180), Early English Gothic (1180–1280), Decorated Gothic (1280–1370), Perpendicular Gothic (1370–1500), Early Tudor (1500–1550), Late Tudor (1550–1600), Palladian Classic (1600–1660), Wren Classic (1660–1700), Georgian (1700–1800), Regency (1800–1837), Victorian (1837–1900), and Modern. Photographically the appeal of each is distinct—from the simple stone masses of the Norman period to the sophisticated elegance of the Regency and the functional excellence of the best Modern styles. Many guide books contain a brief introduction to the various styles.

EQUIPMENT

Any camera can be used to photograph architecture. Even a fixed focus box camera will give excellent photographs providing the photographer is content to let the limitations of the camera dictate the view.

Stand Cameras. For the serious architectural photographer, a stand camera equipped with interchangeable lenses and a complete range of camera movements is essential. Those who wish to take up this form of photography professionally might invest in a whole-plate, but much useful work can be done with a smaller size, e.g., 4 × 5 ins. To increase the extent of the lens movements, the lenses might be mounted off the centre of the lens panel. But lens movements must not be excessive or they will cause "cutting-off" at the extreme corners of the negative.

The falling front is most valuable in photographing church architecture because it allows the lens to be dropped below the base of the plate, to photograph the top of the object, i.e., the top of a font and its base at the same time, to show what the surface plan is like.

Hand Cameras. Ordinary hand cameras are unsuitable for serious architectural photography. The main drawback is the absence of camera movements—in particular, the rising front.

As practically every architectural subject lies mainly above eye level, a camera without an adequate amount of rising front must be tilted upwards at a steep angle and this produces distortion of verticals which is impossible to correct accurately.

Alternatively, either a wide angle lens can be used (if the camera takes interchangeable lenses) or the viewpoint must be moved sufficiently far away to eliminate the tilt. But this means that the negative has to be greatly enlarged (with an inevitable loss of quality).

Miniature Cameras. Although the miniature camera has its limitations in the field of architecture, it has advantages in some directions over the hand camera.

The principal advantage of the miniature for architectural photography is its great depth of field even at wide lens apertures. This enables sharp pictures to be obtained even when a fast shutter speed must be used to arrest the movement of people around the building.

Again, the miniature worker can carry a comprehensive range of lenses which can be quickly interchanged and focused. This allows him to make a complete record of the building in a set of photographs including long shots of distant details and wide angle shots in confined spaces. He can do this in a fraction of the time that would be taken with the conventional equipment.

With a camera taking an oblong negative, e.g., 24 × 36 mm., it is even possible to provide the equivalent of rising front movement by keeping the back of the camera vertical and photographing the subject on the bottom

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

half of the negative. And even when there are uncorrected verticals on the negative, they can be restored to some extent by tilting the negative carrier and easel of the enlarger.

Lenses. A suitable set of lenses for architectural work would be one lens of normal focal length, a wide angle lens and one of longer focal length than the normal. If at all possible, supplementary attachments should be avoided, since the best quality is not achieved with such combinations. Many of the older lenses of quite simple construction can be used to achieve really good results in this field.

Lens Hood. A lens hood should be used always and adjusted afresh for each focal length of lens. The best type for this work has a rectangular shape which just permits the negative area to be covered without cutting off within the field of view. It should be wide enough for the plate when in the horizontal position and tall enough to allow the maximum rise of front without cutting off. Loose pieces of thin black card are useful when photographing detail under brightly lighted windows. A suitable piece is rested on top of the existing hood to cut off any strong beams of light. Exceptionally, it is advisable not to use a lens hood with a wide angle lens and considerable camera movements. The danger of cutting off the negative corners is considerable under such conditions.

Tripod. The most suitable form of tripod has a maximum height of about 5 feet 10 ins. and a minimum of 2 feet with all the legs sliding into one another so that the camera can be adjusted to any height between these two extremes.

Tripods for architectural work should be fitted with a very strong universal ball-joint at the top or a pan and tilt head, providing independent forward backward and side to side tilts of the camera platform.

To prevent the tripod legs from slipping on polished floors there are special rubber feet that fit over the ends of the legs. The same purpose can be served by using three rubber heels, fastened to pieces of wood about 2 ins. square, drilled with holes to take the tripod legs. A mat will also serve the same purpose.

A useful accessory is a small spirit level, to allow the back of the camera to be set accurately in the vertical and horizontal planes. The single bubble type used by engineers is preferable to the circular or T-type sometimes offered for photography, and the casing should be cut away at the sides so that the bubble can be seen at eye level. Some of the better cameras have spirit levels built into the camera body.

Negative Materials. Medium speed, backed panchromatic sheet film, or plates, are the most suitable negative material and in a roll-film camera, a medium speed panchromatic film. These materials have the necessary latitude to deal with the extreme tone range of architectural subjects, and the fine grain for recording detail and texture.

CHURCHES. **Top:** *For general coverage take overlapping views of the whole building, including the previous camera position in each shot.* **Upper Centre:** *If necessary take a second overlapping shot A to ensure covering the earlier camera position. General views can be followed by secondary views B and detail shots. To record the whole of a long wall C take overlapping shots with the camera positions moved parallel to the direction of the wall.* **Lower Centre:** *The eastern end of a church is best photographed from position D between 5 and 7 a.m., the west side from E between 4 and 8 p.m., and the north face from F between 6 and 9 p.m.* **Bottom:** *A complete interior record requires a large number of shots from pre-planned positions.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

One of the great drawbacks of roll film for this work is that it is not possible to develop individual negatives. This is a serious handicap when the subjects on a single film may include contrasty exteriors in bright sunlight and flat, dimly lighted interiors. It is therefore best, when using roll film, to keep conditions of lighting, subject matter, etc., as constant as possible on any single roll.

Filters. Under conditions of blue sky and white cloud, or simply clear blue sky, pleasing results and varying dramatic effects can be achieved by the use of filters—ranging from red to light yellow. Architectural photographs are greatly improved by a definite tone in the sky area. Filters are also often useful in recording the grain in woodwork, or emphasizing the contrast between different materials and, in such places as church interiors, for reproducing coloured inscriptions and illuminated writing, etc.

For shop fronts, highly polished furniture, etc., where reflections are a nuisance, polarizing filters can be very useful. Shop windows also may be photographed by their own lighting, helped out by a flash if necessary so long as the flash is not reflected directly back into the camera lens. It is better to photograph shop windows very late at night, when reflections are at a minimum. The camera can then always be positioned to lessen the effect of unavoidable reflections from street lamps, shop signs, etc.

TECHNIQUE

Before setting up the camera, viewpoint and lighting must be considered.

Viewpoint. Once the viewpoint is chosen, the subject is adjusted to fill the picture space by using a lens of a suitable focal length—not by moving the viewpoint closer to or farther away from the subject (because that would change the perspective).

Lighting. The broad principles of the lighting of outdoor subjects described under daylight apply here. Generally, the best lighting for architectural subjects is sunlight softened by thin clouds and with plenty of reflection from large white cloud masses. Direct sunlight from a cloudless sky gives a hard picture with inky shadows, while the shadowless lighting of an overcast sky loses all the relief and texture of the subject. These faults can be corrected to some extent in development.

The direction of the lighting calls for special attention. Frontal lighting is generally unsuitable because it casts no shadows that can be seen from the camera position and thus does not show in relief the features of the building which stand out towards the camera.

Back lighting again gives no impression of relief to the side of the building facing the camera, and it introduces violent and dramatic contrasts that are out of place in this context.

CHOICE OF FOCAL LENGTH. Left: *A long-focus lens covers a narrow angle of view and reproduces the subject on a large scale from comparatively far away. It is thus suitable for shots of inaccessible detail.* Centre: *The normal lens takes in an average angle and is used for medium views.* Right: *A short-focus lens takes in a wide angle of view, covering a lot of the subject at fairly close range. It is ideal for photographs in confined spaces where it is impossible to back sufficiently from the subject. Extreme wide-angle lenses may, however, produce some image distortion (e.g., the widening of the outside columns in this case).*

CC-0. Agamnigma Digital Preservation Foundation, Chandigarh

As a rule the most suitable lighting is from the side and front at a fairly low angle, e.g., 45 degrees. To emphasize texture at the expense of everything else, it should come from the side and simply skim the surface.

The only way in which the photographer can get the light from the right direction is to choose the right time of day. So for the best results each aspect of the building must be photographed at a different time of day, and a little planning with this in mind will save time and wasted journeys.

Many important buildings including churches and cathedrals are floodlit on special occasions. Pictures of buildings by this form of lighting can be most effective, and provide a valuable supplement to a set taken in daylight.

Perspective. When the lighting conditions are right, the camera is set up at the chosen viewpoint with the baseboard horizontal and the back vertical. The image is roughly focused and examined on the focusing screen. If the top of the building (or the spire or tower of the church) does not come into the picture, it is brought in if possible by raising the camera front. If there is not enough movement available, then front and back swings are used and the baseboard tilted until the subject is all on the screen.

The above procedure takes care of the vertical perspective. Next the horizontal perspective is corrected if necessary, by swinging the back of the camera to produce the most pleasing perspective of the horizontal lines.

If the back is swung to bring it parallel to one face of the building, parallel horizontal lines on that face will reproduce as parallel lines in the print. At the same time, the perspective along the second side of the building may become too steep and it may be necessary to reduce the lateral back swing to an intermediate position giving reasonably good perspective on each face.

At this stage it may be found that the lens has been moved so far off centre that it no longer covers the plate. This is corrected by using front swing until the whole of the picture once more lies inside the area covered and circle of illumination. By this time the focusing screen should show a picture of the building in which all vertical lines are parallel with the sides of the frame and in which the whole subject is included.

Where other features are included in the picture—e.g., trees, or a gateway in the foreground, or hills in the background—their size in relation to the building is controlled by adjusting the distance of the camera from the subject. Moving the camera closer, for instance, would make the objects in the foreground appear larger and the hills in the background smaller in relation to the building. Moving the camera farther away would make the foreground objects appear smaller and the hills larger. The image size must then be adjusted to fill the negative by changing the lens for one

DIRECTION OF THE SUN. To display the structure of a building to its best advantage, the lighting must emphasize its shape. This is governed by the direction of the light, which can only be controlled by waiting for the sun to move to the best position, and then moving the camera position to the best viewpoint. Top: *When the sun is directly behind the camera, everything is evenly lit, and the result is flat and lifeless, without modelling.* Lower centre: *With the sun behind the subject, the shadow side faces the camera and the image consists of nearly detailless silhouettes.* Bottom: *The light from the side throws the subject into relief by casting shadows yet retains highlight and half-tone detail.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

of larger or shorter focal length—i.e., if the negative includes too much of the scenery from the more distant viewpoint, then a lens of longer focal length would confine the picture to a smaller field without changing the perspective.

Focusing. In an architectural photograph, critically sharp focus is expected as a matter of course. The value of the result depends on how much trouble the photographer is prepared to take to focus every detail sharply over the whole area. If the object is simply to make a picture, some softness of outline may even be desirable, but a faithful record must show every feature, including the texture of the building material, with the highest possible standard of definition.

Up to this point, the lens has only been focused roughly; it is now adjusted accurately. First the photographer decides the nearest and farthest planes of the building which are to appear sharply in the final print, i.e., the limits of the depth of field. Next he focuses the lens (at full aperture) on a plane about one-third of the way from the near limit of the depth of field. Finally he stops down the lens until everything appears sharp within the required near and far limits. If overall sharpness is not attained at the desired lens aperture, this may still be done by further tilting the lens panel in the appropriate direction. He then replaces the focusing screen with a loaded plate holder, and makes the exposure normally.

Exposure. Exposure for architectural exteriors can be measured by any of the usual methods and the values are estimated as for other outdoor subjects—e.g., landscapes—making due allowance for such factors as the tone of the subject, the contrast of the scene (including the setting) and the need for reproducing detail in the deepest shadows.

Normally the exposure will be made with a very small stop to achieve the greatest possible depth of field.

Development. Specialists in this field mostly use negative material of a fairly large format and develop by inspection. But the amateur is well advised to stick to his usual developer and adjust his technique to give a clean, fine-grain, not over-contrasty negative. This type of negative will bring out the shadow and highlight detail that is an essential feature of any good architectural record. In extreme cases of halation, however, special developers may be needed.

ARC LAMP. Type of lamps which uses incandescence caused by the passage of an electric current across a gap in a circuit. There are several kinds of arc lamp used in photography and projection.

See also: *Carbon arc lamp; Discharge lamp; Point source lamp; Zirconium lamp.*

ARGENTOTYPE. Early type of positive print invented by Herschel in 1842 which, with slight modifications, formed the basis of the Kallitype and sepia paper processes. The term was at one time also applied to any of the bromide printing processes.

See also: *Printing processes (obsolete).*

ARISTOTYPE. A print made on collodio-chloride paper invented by G. W. Simpson and commercially introduced by J. B. Obernetter of Munich, 1868. The same name was given to Sir W. de W. Abney's gelatin-chloride paper, commercially introduced by Liesegang in Düsseldorf, 1886.

ARMAT, THOMAS, 1866–1919. American inventor (originally an estate agent in Washington, D.C.). Tried to convert the Edison Kinetoscope for projection on to a screen, modified the Demeny Chronophotographe, developed with Jenkins the Phantascope (1895) and exhibited motion pictures with his Vitascope in New York, April 1896 (several months after Lumière showed his Cinematograph in Paris.

ARTIFICIAL LIGHT. Natural light is the light of the sun, moon or stars; all other kinds of lighting are classed as artificial. Electricity provides the principal source of artificial lighting used in photography.

Photographic materials are generally less sensitive to artificial light than to daylight, although in practice the difference is very slight and is dependent on the nature of the light source. However, where accuracy is important, this speed difference must be taken into account, so films often have two speed ratings: one for daylight and one for artificial light by normal filament bulbs.

Exposure for subjects may be either calculated from the type, power and distance of the light, or it may be measured.

There are various types of calculator and tables available for the first method, but there are so many variables that, unless the photographer has some previous experience with the lighting set-up, the results may be no more than 50 per cent satisfactory.

Measurement with an exposure meter is much more reliable—and quicker. At the same time the readings must be taken in such a way that they give a true picture of the illumination reflected in the direction of the camera, and the results must be interpreted intelligently.

Exposures for flash illumination can be calculated fairly satisfactorily from the flash factor of the bulb or electronic outfit in use.

ARTIFICIAL LIGHT HISTORY

Oxy-hydrogen Light (Limelight). The first artificial source of illumination applied to photography in order to shorten the exposure was the limelight invented by Thomas Drummond in 1826.

A jet of oxygen projected through a flame of hydrogen gas impinged on a disk or cylinder of lime, which became brilliantly incandescent. During experiments with this light in the winter and spring of 1839–40, L. L. B. Ibbetson of the Royal Polytechnic Institution, London, succeeded in making in less than 5 minutes a daguerreotype of a piece of coral magnified 12½ times in a microscope—a subject which he stated would have required 25 minutes by sunlight. J. B. Dancer, a well-known microscopist, in July 1840 publicly demonstrated the daguerreotype process at the Liverpool Mechanics' Institution, including taking a daguerreotype of a flea magnified by a gas microscope to fill a 7 × 5 ins. plate.

After chemical acceleration had speeded up the daguerreotype plate, J. F. Goddard photographed a white bust by oxy-hydrogen light with an exposure of 3 minutes in March 1841. Two months later Antoine Claudet took the first portraits from life by artificial light in 15 seconds. (This and other artificial light sources "employed to take portraits at night" were patented by Claudet on 18 December 1841).

These specimens were exhibited at the Royal Institution as a curiosity proving the relative speeds of Goddard's and Claudet's acceleration methods, rather than suggesting the application of limelight to portraiture. Claudet admitted that the light was too harsh, resulting in chalk-white faces.

Limelight was the usual illuminant for optical projection lanterns until after World War I. Since then it has been replaced by electric light.

Pyrotechnic Light. In France, Gaudin and Delamarre patented in 1854 a method of photographing with a kind of Bengal light, with which an exposure of 2 to 3 seconds was sufficient for stereoscopic portraits. A similar pyrotechnic compound of sulphur, potassium nitrate and antimony was used in John Moule's Photogen patented in February 1857 and advertised as "The Rival of the Sun". The object was to make the portrait photographer independent of the weather, and able to work in the evening. The compound when burned in a hexagonal lantern with glass sides produced a brilliant bluish-white light. One side of the lamp had a blue glass screen to protect the sitter from the dazzling light and soften the effect, and it was claimed that better portraits were obtained than with oxy-hydrogen light, though a critic called them "hideous portraits, ghastly and grave-like". The time of combustion was about 15 seconds, during which the exposure was completed, the fumes being carried out of the window by a stove-pipe.

There was a revival of pyrotechnic compound with the Luxograph of Alder and Clarke patented in April 1878. The apparatus had a 4 foot reflector lined with silvered glass, and being fitted with wheels, could easily be moved about. Semi-transparent screens interposed between sitter and light-source softened the effect.

The compound was ignited by a gas jet, and the cost per exposure was stated to be about 2d.—the same as with Moule's Photogen.

Magnesium Light. In 1859 Professor Robert Wilhelm Bunsen (1811–99) of Heidelberg University in collaboration with (Sir) Henry Roscoe reported on the extreme brightness and actinic qualities of burning magnesium wire, and its value for photography. Bunsen devised an apparatus with a spool of magnesium wire unwound by clockwork to bring the end of the wire regularly into contact with the flame of an ordinary spirit-lamp. The first portrait by magnesium light was taken on 22 February 1864 by Alfred Brothers of Manchester, the sitter being Roscoe. Magnesium light was on several occasions used for photography in coal-mines, in the Great Pyramid by C. Piazzi Smyth (1865) and in the Mammoth Caves, Kentucky, by Charles Waldack (1866). Various forms of lamps and reflectors were invented, but almost insuperable objections were the expense of magnesium, as well as the smoke, and magnesium was not much used until the introduction of flashlight powder in 1886. Powdered magnesium had been first proposed in 1865 by W. White, and the idea was revived nearly twenty years later by G. A. Kenyon, suggesting a mixture of powdered magnesium and potassium chlorate. Subsequently this mixture became the most commonly used compound—though some photographers mixed gunpowder with magnesium powder and accidents were not rare! With skill, good results could be obtained, the length of the flash varying according to the compound used from 1/25th to ½ second, using fast gelatin dry plates. The price of magnesium had greatly fallen, but smoke formation remained a great drawback, for the so-called "smokeless" flash powders were only smokeless before ignition.

Attempts were made to catch the smoke in a bag.

Louis Boutan, a specialist in underwater photography, used an electrically ignited magnesium flash lamp designed in 1893 by an electrical engineer named Chauffour. It consisted of coiled magnesium wire in a watertight glass globe containing oxygen, and connected by a fine platinum wire to a battery. When the current was released the platinum wire became red-hot and ignited the magnesium, producing a vivid flash which was intensified by a reflector fixed to the globe. Chauffour's system was a forerunner of the modern smokeless flashbulb

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Louis Boutan's electrically-ignited magnesium flash lamp for underwater photography (1893).

with electric ignition, but it had the disadvantage that as a result of the high temperature the oxygen expanded and burst the globe. The innovation patented by Dr. Paul Vierkoetter in 1925 consisted in avoiding excessive expansion by burning the magnesium wire in a near-vacuum. This improvement eliminated the shattering of the glass bulb. The modern safety flashbulb was introduced, and has been in general use since 1929, when Johannes Ostermeier devised a refinement substituting aluminium wire or foil in oxygen, for the magnesium wire, ribbon, and other shapes specified by Vierkoetter.

Electric Light. Probably the earliest use of electric light for photography was made in 1844 when some of the micro-daguerreotypes of medical specimens taken by Léon Foucault to illustrate Alfred Donné's *Cours de Microscopie* were illuminated by a carbon arc lamp.

In June 1851 Fox Talbot successfully photographed by the flash of a Leyden battery a page of *The Times* fastened to a revolving wheel—a forerunner of stroboscopic light photography.

Three years later Gaudin and Delamarre patented in France a parabolic reflector of silver-plated copper for portrait photography, the light-source being either the pyrotechnic compound already mentioned, or a carbon arc lamp. The eyes of the sitter were protected from the glare by a small concave mirror in front of the carbon points, which threw the light back into the reflector, and by a blue glass screen placed between the light and the sitter. This patent fell into the public domain because the annual payments were not made, which implies that it was not worth keeping on. In fact, the first electric light portrait is claimed to have been taken in 1857 by the St. Petersburg photographer Levitzky with an arc lamp powered by a Bunsen battery consisting of no fewer than 800 elements.

About 1860 Nadar installed a Bunsen battery of 50 elements in his Paris studio, and by 1863 had achieved good results in portraiture with exposures of 60 to 85 seconds, on wet collodion plates, and using white reflectors to light up the shadows. His electric light pictures of the sewers and catacombs of Paris caused a sensation at the International Exhibition in London, 1862.

Adolf Ost of Vienna improved upon Nadar's system by using, instead of white reflecting screens, a smaller lamp powered by 40 Bunsen elements and placed further from the sitter, the main one being powered by 80 elements. Blue glass screens were interposed between the lights and the sitter. Ost arrived at exposures of 7 seconds (using wet collodion), but the running costs of the installation were exceedingly high, so its use was restricted to dark days. Ost showed portraits taken by electric light, up to a size of 13 × 16 ins., at the first photographic exhibition in Vienna in May and June 1864.

Big photomechanical printing firms, and some ordinary photographic establishments, turned to electric light to allow longer working hours. The Woodbury Permanent Photographing Printing Co., for instance, installed about

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

1870 a powerful dynamo to provide the necessary illumination for making gelatin reliefs. Compared with 10 minutes' exposure by sunlight, the 1,200 candle-power electric light required 4 hours to give the same result. The limelight formerly used at this establishment necessitated an exposure of double that time.

The first studio in the world relying exclusively on electric light was opened by Henry Van der Weyde in Regent Street, London, in September 1877. Van der Weyde installed a powerful gas-driven Siemens dynamo in the basement, which supplied current to a carbon arc light of 6,000 candle-power in a 4 foot diameter parabolic reflector fitted with a Fresnel lighthouse lens. To shade the sitter's eyes, a 4 in. concave mirror (similar to Gaudin's and Delamarre's) was fixed in the centre of the reflector, the positive carbon projecting through it. Exposures were stated to be 8 to 10 seconds for "Promenade" portraits ($7\frac{1}{2} \times 3\frac{3}{4}$ ins.) and 2 to 3 seconds for cartes. The Prince of Wales (later Edward VII) set the fashion for having one's portrait taken in evening dress at Van der Weyde's studio, and within a few years similar electric light studios were opened in other European capitals, as well as rival studios in London.

J. E. Mayall's establishment in Bond Street had 12,000 candle-power.

After the introduction of the incandescent filament bulb in 1880, its inventor (Sir) Joseph Wilson Swan expected that electric light for photography would become comparatively inexpensive. However, only a few electricity supply undertakings were formed and public utility electricity did not become general until the present century.

Photoflood. Photoflood lamps of 500 and 1,000 watt power with aluminium reflectors were introduced in the 1920s and have remained an essential light-source in photographic studios and for the photography of architectural interiors and sculpture. A more concentrated beam of light is obtained by using photoflood lamps fitted in spotlights.

Gas Light. As early as 1854 there are references to gas light being used both for taking and printing photographs. Coal-gas is a feeble source of illumination, and being yellowish, weak in actinic rays. Each Bunsen burner with a mantle was equivalent to only about 60 candle-power, and a limit was set to the number of burners by the great heat generated. Nevertheless, a few provincial studios used gas lighting augmented by reflectors, in imitation of the London electric light studios. One of the earliest was that of P. Maitland Laws in Newcastle-on-Tyne, about 1880. He used a Wigham burner with 68 jets yielding 1250 candle-power, a movable reflector lined with silvered glass, and a blue glass screen. Exposures were several times as long as with electric light and Laws regarded the installation only as an auxiliary for the winter season, but his clients were so infected with the craze for artificial light photography that they insisted on gas light portraits even in the middle of the summer.

Gas light was extensively used between about 1885 and 1920 for contact printing on so-called gaslight paper, i.e. chloride and chlorobromide papers.

ARTIGUE PROCESS. Variation of carbon printing, introduced by M. Artigue. In the process no transfer took place and the print was not reversed. The special materials are no longer obtainable.

See also: *Printing processes (obsolete).*

ART PHOTOGRAPHS. Euphemism used in commercial advertising for describing nude or semi-nude studies posed for sex appeal.

A.S.A. SPEED. System of rating the speed of sensitized materials, laid down by the American Standards Association in the A.S.A. standards PH2.5–1960 for black-and-white negative materials and PH2.21–1961 for colour reversal materials. The A.S.A. speed for black-and-white negative emulsions is based on measurement of a prescribed point of the characteristic curve which is at a minimum density level above base + fog density, and satisfies certain conditions of slope. The A.S.A. speed can be expressed either as an arithmetical speed—e.g. A.S.A. 100—or in a logarithmic form where each successive step represents a change in sensitivity by a factor of 2—e.g. A.S.A. 5°. It has become widespread practice to quote both, e.g. A.S.A. 100/5°. This form distinguishes the A.S.A. speed from the older numerically similar exposure index figure.

With reversal colour films the speed is based on a mean exposure derived from two reference points on the characteristic curve, but is expressed in the same way.

Numerically A.S.A. speeds are identical with B.S. speeds as specified by B.S. 1380 : 1962, and related to the speeds specified in the German standard DIN 4512 of 1962.

See also: *Speed of sensitized materials.*

ASPECT RATIO. Shape of the screen image of the projected cine film, expressed in terms of the proportion of the width to the height. Normally this is 4:3 (1·33:1) but is greater with wide-screen motion picture systems—for example 1·8:1, 2·5:1, or even 3:1.

See also: *Projection practice.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

ASPHALT. Another name for bitumen, important in photography as being the substance used by Niépce for making photographs. Asphalt is rendered insoluble in turpentine by the action of light.

ASPHERIC LENS. Term generally applied to optical systems in which one or more lens (or mirror) elements have non-spherical surfaces. An aspheric surface can be described as the deformation of a spherical surface of equal vertex radius. The effect of such deformation, on either a reflecting or refracting surface, is to advance or retard the incident wave-front relative to the action of the spherical surface by itself. Simple examples of such surfaces of revolution are the ellipse, parabola and the hyperbola derived from a conic section (i.e., slicing off the top of a round cone at an angle). Each has particular properties when used as reflecting or refracting surfaces.

SIMPLE ASPHERIC LENS SYSTEM. The non-spherical surfaces (A) are here elliptic, being the surfaces of an ellipsoid.

The use of an aspheric or non-spherical surface can reduce optical aberrations, especially spherical aberration. A related idea is a bispheric lens, which has a spherical surface but with different curvatures in the centre and at the edges. This again helps to bring axial and marginal rays more closely to the same focus. Aspherical surfaces are a powerful tool to the lens designer, and in an established system can lead to a new level of performance. The extra degree of freedom it offers can also lead to a more simplified optical construction resulting in fewer glass elements to achieve a particular result. The "modern" aspheric surface is often a much more complex surface of revolution than any of the conic sections and its use is not restricted to correcting axial aberration only.

SIMPLIFICATION BY ASPHERICS. The use of non-spherical lens surfaces can save lens elements in a design. Thus a typical wide-angle motion picture lens (top) required nine spherical-surfaced elements for an aperture of f 1·8. A redesigned version (bottom) with an aspheric surface uses a more compact lens of seven elements with the same effective light transmission.

ULTRA-SPEED DESIGN. An experimental triplet achieved an aperture of f 0·519 with only five elements, one having an aspheric surface (A). The dotted line indicates the spherical curve.

Economically, aspheric surfaces are more expensive to produce than spherical surfaces, since they must be manufactured singly. However, a particular system need not cost very much more if in using such a surface, several spherical surfaces are eliminated.

One of the more well known applications of an aspheric surface is the corrector plate of a Schmidt mirror system. In the last few years a small number of photographic lenses and lenses for cine and television purposes have utilized aspheric components. Condenser lenses in projectors frequently include one or more components with an aspheric surface. As such lenses are often moulded (or pre-moulded) rather than ground, and the required standard of precision lower, this manufacture is not appreciably more expensive than for normal condenser lenses. P.A.M.

ASSOCIATION OF CINEMATOGRAPH, TELEVISION AND ALLIED TECHNICIANS. The Association of Cine and Allied Technicians was founded in 1933 and registered as a trade union in the same year. Its aims and activities correspond to those of other trades unions, and are devoted to the interests of those employed in the motion picture industry and in television. Membership is normally open to film technicians engaged in film production and film processing, including directors, cameramen, sound recording engineers, art directors, editors and assisting

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

grades. Similar grades employed in Digital Preservation Foundation, Chandigarh are also eligible for membership. The Association has negotiated agreements on pay and working conditions with employers in features, newsreel and short films, and also in film processing.

It is affiliated to the Trades Union Congress and the Labour Party.

The Association is governed by a General Council representing all grades, members of the Council being elected by ballot at the annual conference where policy is also decided.

Membership of the Association in 1963 was 11,637. Entry to most grades is dependent upon employment conditions in the industry.

The official publication of the Association, the *Film and TV Technician*, is issued monthly.

ASTIGMATISM. One of the off-axis aberrations of lenses which makes the lens reproduce a point light source as two lines at right angles lying in different focal planes.

See also: *Aberrations of lenses; Lens performance; Lens testing.*

ASTRONOMY

Astronomical photography is concerned with the photography of everything that lies outside the earth's atmosphere. From the beginnings of photography, photographic science and astronomy have been closely linked (the word *photography* was coined by the astronomer John Herschel). The first successful daguerrotype of the sun's disc was made in 1845, but it was the introduction of the dry emulsion plate about 1875–80 that revolutionized astronomy. Since then, much of our vast increase in knowledge of the Universe has come by the application of photography. Although some measurements of the brightnesses of stars and other objects have recently been made more accurately by photoelectric methods, photography is likely to remain a major technique in astronomy for many years. In return, the exacting demands of the astronomer for materials sensitive to weak light fluxes and to particular wavelengths have stimulated many improvements in the manufacture of emulsions that have had applications in other fields.

Photography has various advantages to the astronomer; the following are the more important.

(1) The sensitive emulsion can add up the light received over a period and thus give an image of a celestial object that does not emit enough light to make it visible to the eye even through the most powerful telescope.

(2) Sensitive materials can be manufactured with a wider range of colour response than that of the human eye (e.g. ultra-violet and infra-red).

(3) The camera gives a permanent record of transient events.

Modern Apparatus. Four main forms of camera (or telescope adapted for photography) are used for different purposes:

(1) Refracting telescope. With an achromatic doublet lens working at about *f* 12 to *f* 15: the largest (Yerkes Observatory, Wisconsin) has a 40 in. diameter lens. It is used for photography of the moon and planets, and the very accurate measurement of the positions of stars to determine their distance by the parallax method.

(2) Reflecting telescope. The image is formed at the focus of a parabolic mirror, typically of about *f* 5. The telescope is perfectly achromatic, and the mirror can be made very large to gather much light and so enable faint objects to be studied. The useful field is however severely limited by coma to about ½°, even if a correcting lens is placed just in front of the photographic plate. Reflecting telescopes are the most generally used equipment today for the study of individual stars and the more distant galaxies. The largest (Hale telescope, Palomar Mountain Observatory) has a mirror 200 ins. in diameter working at *f* 3·3.

(3) Astrographic camera. The lens is relatively small (typically 5 to 10 ins. diameter) and of three or four components, to give a working field several degrees in diameter at about *f* 8. It is used to measure accurately the relative positions of stars and their motions with respect to one another over periods of years.

(4) Schmidt camera. This ingenious design of camera was announced by Bernhard Schmidt in 1932. It is primarily a reflecting telescope, with all its advantages. The mirror is however spherical, and a thin corrector plate (a weak aspherical lens) at the centre of curvature of the mirror removes the spherical aberration and coma without introducing significant chromatic aberration. It can be made in large sizes to work at about *f* 3 and give essentially perfect images of stars over a field of several degrees. Used for survey work it can reach much fainter stars than the astrographic camera. The largest camera has a corrector plate a little over 48 ins. in diameter and works at *f* 2·5 (Palomar Schmidt).

Other instruments are used for specialized purposes, e.g. lenses and mirrors of great focal length (100 feet or more) for solar work, and fast super-Schmidt designs (20 ins. aperture, *f* 1·5) for recording meteors and artificial satellites.

Since celestial objects move across the sky because of the rotation of the earth, most large telescopes are mounted on equatorial mountings that follow the objects automatically during the long exposure. The polar axis of these mountings is parallel to the axis of rota-

CC-0. Vigyan Digital Preservation Foundation, Chandigarh

tion of the earth, and is driven in the contrary direction by an accurate clock.

The precision required of astronomical equipment, in both optics and mounting, is the most exacting of any form of photography. Stars are effectively perfect points of light at infinity, and must be recorded as small symmetrical images alike at the centre and at the edge of the photographic plate. Most lenses designed for pictorial work of the highest quality, or even for photogrammetry, show intolerable defects when attempts are made to apply them to astronomy. Moreover the quantitative interpretation of the astronomical negatives, by such methods as densitometry to give the brightnesses of stars, etc., requires the most meticulous attention to cleanliness in working, uniformity of development, and reproducibility of processing techniques. Most practical astronomers are necessarily skilled technical photographers.

Spectrographs. The study of the composition of the light from celestial objects gives information about the temperature, constitution, and chemical composition of the source. In addition the measured wavelengths of features in the spectrum reveal the velocity of the object. A line in the spectrum is displaced in wavelength by an amount directly proportional to the velocity, to the red end of the spectrum if the object is receding. Spectrography is therefore a most important branch of astrophysics. Usually a reflecting telescope is used to image the star or other object on to the slit of a spectrograph.

EQUATORIAL MOUNTING, carrying a telescope and small camera. The rotation of the polar axis once a day compensates for the rotation of the earth and makes the telescope follow the apparent motion of the stars. A, camera; B, plateholder; C, finder telescope; D, eyepiece focusing knob; E, polar axis (angle of elevation = latitude of observatory); F, telescope eyepiece; G, objective lens and dew cap; H, polar axis with right ascension circle; I, declination circle; J, counter weight; K, declination axis; L, driving clock.

In modern work reflecting diffraction gratings are found more efficient than prisms. The spectrum so formed is photographed with cameras: all-mirror optics are used for work in the ultra-violet region, and small fast Schmidt cameras for faint light sources.

Emulsions. The choice of emulsion for any particular photograph depends on such factors as the brightness of the object, the wavelength region to be studied, the steadiness of the earth's atmosphere, the aperture and the focal length of the telescope, and the purpose of the photograph. The resolving power and dispersion of the spectrograph are also relevant. In the past empirical experience played a large part in the choice; more recently progress has been made in choosing materials for their informational sensitivity characteristics, by the application of information theory to the imaging and photographic processes.

Although astronomical objects cover an enormous brightness range the indisposable factor is usually the extreme faintness of the objects to be studied. Even with the largest telescopes and the most sensitive emulsions exposures may run to several hours. For such work all other considerations must be sacrificed to that of speed, even though the emulsion for any other purpose would have an intolerably coarse grain. Emulsions considered fast in commercial and pictorial work are useless because of the failure of the reciprocity law for long exposures. Special emulsions with low reciprocity failure are used. The speed of some emulsions can also be increased by such techniques as pre-flashing or baking (heating at about 60°C for some hours) before the exposure. Colour sensitized (dyed) emulsions are used in limited wavelength regions.

Although spectacular colour photographs of a few objects have been taken, the low speed and small exposure range of colour reversal and similar processes have limited the application of direct colour photography in astronomy.

BRIGHTNESS OF CELESTIAL OBJECTS

Object	*Magnitude*	*Relative Brightness*
Sun	− 26	10^{10}
Moon	− 11	10^{4}
Stars:		
Brightest	− 1	1
Faintest visible with naked eye	+ 6	$1{\cdot}6 \times 10^{-3}$
Faintest photographed	+ 22	6×10^{-10}

The magnitude scale is logarithmic. An interval of 5 magnitudes corresponds to a factor of 100 in brightness; 1 magnitude = 2·512 in brightness.

The Sun. The sun is the only star near enough for its surface to be investigated in detail.

Direct photography of the sun is of two types:

(1) photography in white light to record sunspots and the finer structure, called granulation, on the disc;

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

(2) photographs in very narrow wavelength regions centred on such Fraunhofer lines as the red *C* line of hydrogen at 6563 A, which show the distribution of that element in the solar atmosphere and such features as prominences and flares.

The earth's atmosphere is normally turbulent because it is not of uniform temperature, and small irregularities of refractive index blur the finest detail: exposures on the disc are therefore kept short (0.001 second) to "freeze" the image, and there is sufficient light to use fine grain plates of high contrast.

Photographs in the light of a single wavelength (spectroheliograms) are taken with scanning spectrographs or through narrow band filters of the Lyot type, using a suitable colour-sensitized emulsion. They show the prominences and flares that are features of the chromosphere, the lowest layer in the solar atmosphere.

Above this is the still fainter corona which constitutes the outer atmosphere of the sun. This could originally be studied only during total eclipses. A coronagraph is a telescope designed to minimize scattered light and produce an artificial eclipse; used at high altitude observatories, it enables the brighter inner corona to be photographed hour by hour in good sky conditions. The first coronagraph was designed by Bernard Lyot and was installed at the Pic-du-Midi Observatory, in the Pyrenees, in 1935. Time lapse films of prominence and coronal activity have been made.

Some investigations, however, must still be made during the brief few minutes of a total eclipse of the sun. Suitable eclipses occur every few years and require an expedition to the narrow band on the earth's surface where the eclipse is total. Exacting photographic requirements have often to be met under tropical or other extreme conditions, with poor water supply, dust, etc.

It is not possible to record all the various luminous zones around the sun on one photographic plate because the range of brightness is too great. The prominences and more intense features near the surface of the sun can be photographed in a few seconds but the long streamers that reach out for great distances into space need much longer exposures.

The Moon. J. W. Draper first photographed the moon in March 1840, shortly after the invention of photography. Detailed photographs of the surface of the moon are usually taken near the terminator (the boundary between the illuminated and dark parts). On these parts of the moon's surface the sun is just rising or setting, and hence mountains, craters, etc., are thrown into relief. Turbulence in the earth's atmosphere at night still produces blurring of the image, though it is less serious than in the daytime. Typical exposures are one or two seconds. The smallest features detectable have dimensions of a few hundred yards.

A most striking recent feat has been the photography of the coarser features of that area of the moon's surface that is invisible from the earth. This was achieved by the Russian Automatic Interplanetary Station (AIS) which passed behind the moon in October 1959. The AIS carried two cameras with 200 mm. (*f* 5·6) and 500 mm. (*f* 9·5) lenses respectively, which were automatically directed at the moon. The photographs were processed and dried in the AIS, and were then transmitted to the earth by radio, for reconstruction by methods analagous to those used in the formation of a picture on a television screen.

The Planets. Of the principal planets of the solar system only the brighter (Venus, Mars, Jupiter and Saturn) have discs large enough to show appreciable detail, and these have been extensively studied. Mercury, Uranus and Neptune are difficult subjects and Pluto is too small to show a photographable disc.

The first photographs to show planetary surface markings, of Mars and Jupiter, were taken independently by B. A. Gould and A. A. Common in 1879.

The method and exposures are generally similar to those used for the moon. Mars shows some features similar to the earth, with an atmosphere, clouds, and markings on the solid surface. Photographs in blue light show clouds and atmospheric features, red and infra-red rays penetrate the atmosphere and show surface markings. The cloud layers on Venus are too dense for even infra-red rays to penetrate to the surface. Spectrography gives indications of the gaseous constituents of the atmospheres of the planets.

The minor planets, orbiting between Mars and Jupiter, are too small to show a disc and appear star-like: they are detected by their motion against the background of the stars on photographs taken with astrographs or Schmidt cameras. The equatorially mounted camera, driven to follow the stars, records the stars as point images, but the minor planets give elongated trails because they move during the long exposure.

Astrometry. Although moving through space with velocities up to a few hundred kilometres a second, the stars are so distant that their relative motion in the sky is very difficult to detect. A typical value is 0·1 second of arc in ten years, and even with cameras of long focus the displacement of the star images may be only a few thousandths of a millimetre from one negative to another taken several years later. Great care must be taken to maintain the exact adjustment of the lenses of the astrographic camera during the interval. Careful processing and drying are necessary to avoid distorting the emulsion when it is still wet and soft, and plates must also be stored in suitable conditions since they may be needed for measurement decades later.

Sky Surveys. The light gathering power and wide field of the Schmidt cameras have enabled

CC-0. Ananthapur Digital Preservation Foundation, Chandigarh

surveys of the sky to magnitude limits: they are thus surveys of the Universe to great distances. The most comprehensive is the National Geographic Society—Palomar Survey, covering the whole sky visible to the 48 inch Schmidt camera. It records tens of millions of stars and galaxies down to 20^m, the more distant galaxies being at least 3×10^9 light years away and receding at velocities of one-third the velocity of light. Contact print copies of the Survey are in the world's principal observatories. Individual objects of interest can be selected from these surveys for detailed study with reflectors and spectrographs.

Artificial Satellites. Most of the work of tracking rockets and satellites in the first stages of flight after launching is similar to the techniques of missile photography and uses special long focus camera systems.

Once the satellite is above the atmosphere and in free flight the precise orbit must be obtained, and small changes in the orbit determined from time to time. Photographs are therefore required which show the track and velocity of the satellite, rather than details of the object itself. When in orbit most of the artificial satellites are faint objects, and to photograph them cameras of large linear aperture are required: the field must also be large since the satellites are moving relatively quickly.

Schmidt cameras are evidently suitable,and one of the cameras developed for this work is a modified Schmidt design with a 31 ins. mirror working at *f* 1·0. A crystal clock photographed on to the same film frame can be read to 0·1 millisecond, and the expected accuracy of the observation is 2 seconds of arc at 1 millisecond. A 6 ins. satellite has been recorded in this way at a distance of 2,500 miles.

One method of determining the path and velocity is to mount the camera on the usual equatorial mounting and drive it to keep the star images stationary on the film. The moving satellite then appears as a line of light against the star background. The exposure is interrupted at regular and accurately determined times so that the image of the satellite appears as a dashed line on the film. The length and mid-point of each dash gives the instantaneous velocity and position of the satellite.

To be of scientific value amateur photographs of satellites must satisfy certain minimum conditions, specified by the Society of Photographic Scientists and Engineers as follows:

The camera should take negatives of at least 5 ins. The sensitive material should have an emulsion speed of at least 200 ASA, and the satellite should be photographed against a star background (preferably a well known constellation for easy recognition), with two gaps in the track timed to 0·1 second.

Photography from Balloons and Rockets. Turbulence in the atmosphere near the earth produces blurring of the images of celestial objects, and prevents the photography of the finest detail. The highest accessible mountain sites do not remove this difficulty. Since 1957 a group of Princeton University astronomers have made successful observations with a 12 ins. aperture telescope which is carried to heights above 80,000 feet by an unmanned balloon. The balloons are huge envelopes of plastic film which, containing a small amount of helium gas at launching, expand to their full size at altitude. The telescope is automatically guided on the sun and operated by remote radio control. At the end of each flight the telescope is returned to earth by parachute, or by releasing gas from the balloon.

A similar telescope of 36 ins. aperture for photography of stars and planets is now used.

The earth's atmosphere is also opaque to ultra-violet radiation below about 3,300 A, but this interesting region of the spectrum is becoming accessible to cameras and spectrographs mounted in rockets and satellites. Most of the negatives so obtained, e.g. of the ultra-violet spectrum of the sun, have been exposed in rockets above the atmosphere and processed after recovery from the fallen rocket. The practical difficulties of research in space are immense, and space research will not make terrestrial telescopes obsolete in the foreseeable future. The application of image intensifier devices to terrestrial telescopes may yield results as important as space research. These devices are interposed between the primary image, formed by the telescope, and the photographic plate; they amplify the incident light signal by photoelectric methods. Various types are undergoing development and useful results have been obtained. This seems a more promising approach than attempts to make even larger reflecting telescopes. D.W.D. & G.T.S.

Books: *Astronomical Photography*, by G. de Vaucouleurs (London), historical and general; *Stars and Stellar Systems: Vol. I, Techniques*, edited by W. A. Hiltner (Chicago), advanced text; *Astronomical Photography for the Amateur*, by T. Rackham (London).

ATGET, JEAN EUGÈNE AUGUSTE, 1857–1927. French actor and photographer. Specialized in picturing Paris from 1898 onwards; the artistic and documentary value of his photographs was recognized only after his death. Biographies: *Atget, Photographe de Paris*, by Pierre Mac-Orlan (Paris 1930); *World of Atget* by B. Abbott (New York 1964).

ATMOSPHERE. That quality in a photograph which evokes the natural sensations associated with particular scenes. The atmosphere of a March landscape might be conveyed by a cold, clear sky, pale sunshine, bare, wind-blown branches and scurrying clouds. A cathedral interior would possess atmosphere if, by subdued tones and distant, highlighted

windows, it suggested the characteristic echoing twilight of such places.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

ATMOSPHERIC ACTION. Action of the air on photographic materials which generally causes slow deterioration. In addition to active oxygen which is particularly damaging to developers, the air may contain varying amounts of harmful impurities such as sulphur, suspended moisture and dust, and many kinds of industrial fume and smoke. For this reason all sensitive materials should be kept out of contact with free air as much as possible.

See also: *Fogging.*

ATOMIC THEORY. Supposition that all matter consists of basic and chemically indivisible units, the atoms. During chemical reactions they combine with each other in proportions that are either simple or a multiple of the number of atoms involved.

AUDIO-VISUAL AIDS. Equipment and systems for projecting pictures with or without sound accompaniment, used as an aid to teaching, instruction and training. "Audio-visual" implies the use of both sound and image.

Aids of this nature cover cine film in 8 and 16 mm., especially with optical or magnetic sound tracks; film strips and slides and projectors for them, as well as tape recorders used to provide a sound commentary and/or control the picture presentation; finally closed circuit television systems used for education and instruction.

See also: *Visual Aids.*

AUSTRALIA. Australia as a nation can be said to have grown up with photography. Records show that an experiment in daguerrotype photography (a street scene) was made by a visitor from France as early as May 1841 while in the following year (9th December to be exact) the first professional daguerrotypist, G. B. Goodman, had set himself up in business in a studio on the roof of the Royal Hotel, Sydney. Goodman subsequently travelled Australia visiting all the principal centres and taking the new portraits which attracted much public attention. Technical developments in photography reached Australia fairly quickly and by the early fifties a number of permanent businesses had been established in all the towns which are now the state capitals. In Sydney the photographic work of such men as Oswald Allen, W. Bradley, W. Hetzer, Thomas B. Glaister, Edward Dalton, Wheeler and W. C. W. Freeman was acclaimed as being the equal of any in the world. In Melbourne the new art was associated with the names of Townsend Duryea, P. M. Batchelder, T. A. Hill, John Noon, W. Asquith, W. W. Pentland, Antoine Fauchery, Davis & Co., and Burman.

Early Exhibitions. Amateurs were soon active and by the year 1858, interest had grown sufficiently for a display of photographs to be held by the Sydney Philosophical Society; on this occasion, in addition to many photographs by the above-mentioned Sydney professionals, examples were displayed by a number of amateurs—these including Professor J. Smith, Stanley Jevons and R. Hunt, the latter two being officers of the then newly-established Sydney Royal Mint. Large collections of either negatives or prints by these three workers have survived and may well represent the world's most important collections of early amateur photography. Active, although not an exhibitor on this occasion, was Sir William MacArthur of Camden, believed to be the first Australian-born photographer.

Historical Collections. A comparatively large cross-section of early photography of all types has been preserved in Australia, and most state libraries, as well as the Australian National Library at Canberra, show increasing interest in this subject. Two of the most important collections are perhaps that of Professor John Smith, who came from Aberdeen (*c.* 1857) to be first Professor of Chemistry at Sydney University and who recorded photographically the growth of his University, and the Holterman Collection, which was brought to public notice by the Australasian Photo-Review in 1953. The latter collection comprises several thousand original negatives of the period 1872–83. Under the sponsorship of the gold miner, Bernard Otto Holtermann (famous for his discovery of the world's greatest specimen of reef gold) photographers Beaufoy Merlin and Charles Bayliss covered all the principal towns of the south-east of the continent, besides producing many hundreds of negatives representing a complete portrayal of life on the Hill End and Gulgong goldfields in 1872. So complete are these two last-named series that it has been possible to effect perfect reconstructions of the two towns. The collection now in The Mitchell Library (Sydney), includes the largest negatives ever made by the wet plate process.

All historical aspects are now being actively attended to by the Historical Committee of the Australian Photographic Society and by a large number of state libraries and by the National Library at Canberra, which has already acquired important collections representing the work of most of our pioneer pictorialists.

Technical and Manufacturing Progress. Australia can claim at least four "firsts" in photography. These include the first practical photolithography (by James W. Osborne, Victorian Government Photographer, in September, 1859, and also by John Degotardi of Sydney); the first high-quality method of half-tone photo-reproduction (the Woodburytype, by Walter Woodbury, 1864) the full length feature film (by Ensign Perry of the Salvation

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Army, Melbourne, 1900, being Commandant Herbert Booth's *Soldiers of the Cross*) and the first film for children (*Kidstakes*, *c.* 1930). *Soldiers of the Cross* also featured colour, which was introduced by means of hand-coloured lantern slides during the changing of the reels.

Commercial dry plates began to reach Australia in the early eighties while the first Australian-made plates appeared *c.* 1883–4 when Thomas Baker opened a small factory for the coating of Austral Dry Plates. A little later he entered into partnership with J. J. Rouse and established shops in several centres. By the turn of the century, the partnership was representing the Eastman Kodak Co. in Australia and about 1907 became a Kodak subsidiary as did, about twenty years later, the only other large distributing organization, Harringtons Ltd., which had ceased manufacturing during World War I. Today at Coburg there is a modern forty acre plant in which is coated a wide variety of sensitized materials. The production programme also covers a range of accessories, and chemical preparations for amateur, professional and specialized uses, as well as colour film processing. Various firms make photographic and other lenses and ranges of modern slide projectors. Local packaging is undertaken by leading importers and there are a large number of modern colour processing laboratories catering for the increasing public interest.

Applications. In every department of life, Australia may be regarded as a most photographically-minded country. Possibly the most characteristically Australian aspect of scientific photography lies in the fields of cosmic rays and radio astronomy. In the clinical photography of operative surgery, the photographic technicians of the leading hospitals are recognized as being amongst the world's foremost, considerable progress having been made with many special techniques, including the production of stereoscopic colour films. Governmental agricultural, forestry and soil conservation services use photography extensively. There has been great added scope for advanced technical photography through such projects as the Snowy Mountain Hydro-Electric Scheme and the Long Range Weapons Establishment at Woomera, S.A.

Recent research work has led to improvement in the electrophotographic process—in particular, to the invention of liquid development of the latent electrostatic image (thereby enabling the process to be extended to full colour printing) and to the establishment of new coating techniques based upon a chargeless system. These processes have now been internationally patented.

A forward step in the field of projection has resulted in a well-defined and exciting art form in which symbolical and exciting abstract slides dissolve into each other to the accompaniment of electronic music. A further recent development involves the use of revolving polaroid filters.

Photographers and Organizations. Pictorial photography has been followed in Australia for almost one hundred years. Its greatest period was in the mid-twenties when the salons of the world were distinguished by the contributions of Dr. Julian Smith, Harold Cazneaux, John B. Eaton, Norman Deck, and Henri Mallard.

The Australian Photographic Society was established in 1961 and rapidly achieved full status as the co-ordinating body for Australian Photography both nationally and internationally. Its forerunner, the Australian Photographic Federation continues as a division linking the governing bodies of the camera club movement in every state; it compromises the Photographic Society of Queensland, Federation of Camera Clubs (N.S.W.), Canberra Photographic Society, Victorian Association of Photographic Societies, Tasmanian Photographic Federation, South Australian Photographic Federation, Western Australian Photographic Federation together with Australian Portfolio Photographic Society and the Stereoscopic Society, Australian section. Through direct membership of the A.P.S. and its 350 affiliated camera clubs, more than 6,000 photographers are now linked together and thereby associated with the F.I.A.P.

A large number of national and international exhibitions are regularly held. The A.P.S. will eventually issue its own honours but, in the meantime, a start is being made with awards of medals and plaques of striking national design.

Increased interest in exhibitions has resulted in greater support by Australians to overseas salons. Our most notable successes are those associated with natural history photography and colour photography. Australia continues to supply an increasing proportion of the entries in Asian Exhibitions and also receives important support from those countries for its own salons. In addition there are amateur cine societies, trade and professional associations.

Publications. Portfolios apart, there have been few purely photographic volumes published in Australia. Outstanding is Jack Cato's monumental *The Story of the Camera in Australia*—an authoritative volume of over 200 pages of letterpress and seventy-six pages of illustrations, published in December 1955.

The longest established journal, *The Australasian Photo-Review*, ceased publication in 1956, its 63rd year. Photographic magazines now being published are the monthlies *Australian Photography* and *Camera World*, and the quarterly *Industrial Photography*. There are two trade monthlies, while the journal *Professional Photography* represents the official organ for the professional photographer.

K.B. & A.R.A.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

AUSTRIA

Austria has made a valuable contribution to the progress of photography, notably through the activities of certain photographic organizations in Austria—some of which are almost as old as photography itself. Among the individuals who are prominent for their contribution to basic research, the names of Petzval, Eder, Valenta and Schinzel are particularly worthy of mention.

The history of photography in Austria began in the year 1839, when von Ettingshausen, professor of Physics at Vienna University, returned from Paris where he had learned Daguerre's process from the inventor himself. He passed his knowledge on to his friends, who formed the nucleus from which the whole Austrian photographic movement evolved.

Inventions and Discoveries. In 1840 the Viennese mathematician, Josef M. Petzval, computed his portrait lens. It has since become world famous, and even today its aperture of *f* 3·6 is noteworthy. In the same year the Viennese, Franz Kratochwila, succeeded in increasing the sensitivity of photographic plates five times by exposing them to bromide and chloride vapours, as well as the iodine vapour used by Daguerre. The combined effect of these improvements was to reduce the long exposure times of 15 minutes or more to a matter of seconds, thus greatly facilitating portrait photography. Petzval's lens was manufactured in Vienna by Peter Friedrich Voigtländer in 1841.

In 1876 Josef Maria Eder (1855–1944), introduced important improvements in the collodion process. The daguerrotype and Fox Talbot's calotype were superseded by Scott Archer's collodion process. Eder now discovered that the keeping properties and sensitivity of collodion plates could both be considerably enhanced by means of the new cadmium double salts which he had discovered. The discovery was awarded a bronze medal at the 1878 World Exhibition in Paris.

In collaboration with von Tóth, Eder evolved a new method of intensifying collodion negatives with lead salts and potassium ferricyanide, which was published under the name of lead intensification. The two men also performed pioneering work on toning processes, in the course of which they demonstrated that by converting the silver image to silver ferrocyanide, it was then possible to dye it in various colours by the use of metallic chlorides. Their work laid the foundations of all later toning processes.

In 1880 Eder and G. Pizzighelli introduced an important improvement in the method of preparing the dry plate by their invention of the silver oxide ammonia method, which is still in use today. This method combines the advantages of rapid working and low ripening temperature, and produces vigorous, clear negatives.

In the same year Eder and von Tóth discovered pyrocatechin as a developing agent for silver bromide gelatin emulsions. Together with the discovery of the developing properties of hydroquinone by the Englishman, Abney, this achievement headed the long list of organic developers.

In 1881, Eder and Pizzighelli invented a method of making positive plates and gaslight papers of low sensitivity with pure silver chloride emulsion requiring alkaline development. Hitherto only printing-out papers, using excess silver nitrate, had been known. Twelve years later this discovery was popularized throughout the world by the Americans in the form of Velox silver chloride paper. Eder later also introduced chlorobromide paper, which was first manufactured commercially in England and is today the standard emulsion for the warm-tone papers popularly used by pictorial photographers.

In 1884 Eder discovered that erythrosin among the eosin group of coal-tar dyes was a particularly good green and yellow sensitizer. He thereby succeeded in making the first orthochromatic emulsion, the term orthochromatic itself being coined in Vienna at that time. Shortly after this discovery the manufacture of orthochromatic erythrosin plates began throughout the world.

In 1889 Professor Eduard Valenta found that glycin red could act as a sensitizing dye for the red-orange spectral region. Six years later, only one year after Rœntgen's discovery of X-rays, Valenta in collaboration with Eder produced a series of unique works on photographic science entitled *Röntgenphotographie*, also an *Atlas Typischer Spektren* (Atlas of Typical Spectra) and, in 1904 *Beiträge zur Photochemie und Spektralanalyse* (Contributions to photographic chemistry and spectral analysis).

In 1898 Eder read a paper to the third International Congress on Applied Chemistry in Vienna on the principles of a standard sensitometer. His paper brought about the use of Scheiner's Sensitometer for determining sensitometric standards.

In 1906 Theodor Scheimpflug invented a device for eliminating distortion in aerial photographs which he called a photoperspectograph. His invention was published in a paper entitled *Die Herstellung von Karten und Plänen auf photographischem Wege* (Map and Plan Making by Photography) which still stands as an exposition of the essentials of aerial photogrammetry.

In 1919 Eder and Hecht produced a new grey scale wedge sensitometer for determining emulsion speeds. This had become necessary owing to the constant increase in the speed of photographic materials during the first World War.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Among Eder's considerable literary output mention must be made of his *Ausführliches Handbuch der Photographie* (Comprehensive Handbook of Photography), which was first published in 1884. Many accounts of his extensive work on photographic science were published in the *Photographische Korrespondenz*, the organ of the Photographische Gesellschaft (Photographic Society).

In 1922 the Viennese, Otto Schuloff, discovered pinaflavol as a green sensitizer, which led to still further improvement in orthochromatic plates. At the same time he discovered the desensitizing properties of the pinacryptol group of dyes.

In the field of colour photography Dr. Karl Schinzel (1886–1951) in 1905 suggested a method of colour photography involving three superimposed emulsions sensitized respectively for the primary colours, blue, green and red and dyed in the complementary colours. Schinzel's idea is the basis of integral tripack colour film which was to sweep the world thirty years later. In 1936 Schinzel published a series of articles on colour photography involving tripack materials and colour development, which examined the whole question from the chemical point of view.

Josef Rheden (died 1946), an astronomer at the Wiener Universitätssternwarte (Vienna University Observatory) made a number of contributions to photography. Over a period of 25 years he took well over 2,000 photographs of small planets, star clusters, nebulae, comets and the Milky Way, which aroused much interest among specialists. Rheden was one of the first to use a miniature camera for photographing nebulae and star clusters. His purpose was to obtain a reduced, point-size image from which to measure the brightness of the star by photographic means. He also worked on sensitometry, and by means of latensification succeeded for the first time in photographing a number of very weak stars, without increase of exposure. Rheden's name became widely known through his exposure tables which still retain their value today and, together with the accompanying instructions, these tables can legitimately be described as unique. In the form of a small pocket book, the tables give full data for every half-hour of the day, for all latitudes, from sunrise to sunset throughout the year, and for a multitude of different subjects.

Organizations and Institutions. Die Photographische Gesellschaft (The Photographic Society) which was founded in 1861 in the Wiener Akademie der Wissenschaften (Vienna Academy of Science) has played a leading part in guiding the progress of photography from the beginning. Its first president was Anton Martin, author of the first German language manual of photography (apart from Daguerre manuals), the *Repertorium der Photographie*, which appeared as early as 1846. The Society has always been active in promoting study of both the theoretical and the practical aspects of photography. In 1864 it organized in Vienna the first exhibition of photographs to be held in German-speaking Europe, and innumerable exhibitions have followed up to the present time. Members of the Society have won the highest awards in foreign exhibitions of pictorial photography; and a series of grants enabled the Society to offer awards for distinguished services and achievements in photography and other closely related fields. It is noteworthy that the greater part of these awards and grants have been made to foreigners.

The Society worked to obtain legal backing for protection of copyright in photographic work, and its efforts were successful at the turn of the last century. It also influenced foreign copyright legislation.

In 1906 the Society obtained a charter from Emperor Francis Joseph I with the right to call itself the Kaiserlich-königliche Photographische Gesellschaft (Imperial and Royal Photographic Society) and to use the Austrian coat of arms. The Republic later confirmed the Society's claim to the latter privilege.

The Graphische Lehr- und Versuchsanstalt (Graphic Arts Institute) had its origin in the photographic department of the then existing Höhere Staatsgewerbeschule (Higher State Training School), which, however, had more the character of a scientific research department. Eder therefore put forward plans in 1885 for an establishment which would both pursue research and offer training in the profession of photography. The Institute was duly opened on 1st March, 1888, on the premises of a former school under the leadership of Eder, who had meanwhile been appointed Professor of Chemistry at the Wiener Technische Hochschule (Vienna Technical College). Its main activities at the outset, which it has maintained to this day, are professional training, scientific research, and the attainment of high technical and artistic standards. In the succeeding years a number of additional departments were formed, the valuable collections were increased, and the library is today recognized as one of the most complete collections of technical reference books, particularly in the field of photography.

The journal *Photographische Korrespondenz* (Photographic Review), founded by Ludwig Schrank in 1864, is the official organ both of the Photographische Gesellschaft and of the Graphische Lehr- und Versuchsanstalt.

The Austrian Stereoskopische Gesellschaft (Stereoscopic Society) which meets in the Graphic Arts Institute, was formed in 1928 to encourage and promote stereoscopy, stereo photography and stereo projection. It is noteworthy that polarized light has been used for projection at the Society's meetings since about 1940.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Research Laboratories. Austria has two research establishments for specialized branches of photography. The Mikrobiologische Station der Stadt Linz (Linz Microbiological Station) was founded in 1953 to continue the work of the Vienna Forschungslaboratorium für Wissenschaftliche and Angewandte Mikroskopie, Mikrophotographie und Mikrokinematographie (Research Laboratory for Scientific and Applied Microscopy, Photomicrography and Kinemicrography) founded 1921. The Linz establishment is mainly concerned with photographic and cinematographic recording of micro-organisms and their life cycle, in particular by means of Schild's method of dish microscopy.

The Versuchs- und Forschungslaboratorium für Infrarot-Photographie (Experimental and Research Laboratory for Infra-Red Photography) founded in Vienna in 1933 is active in the natural sciences and technology, and is mainly concerned with new applications in these fields.

Industry. The principal Austrian products are photographic papers (one firm), plates (one firm) and chemicals. In addition, well-known sub-standard cine cameras and projectors are produced by one firm. Production of still cameras and accessories is on a smaller scale. Austria depends to a large extent on imports of apparatus and sensitive materials, particularly films, of which there is no domestic production.

Professional Photography. In the early days in Austria, as in other countries, photographs were taken by persons of the most varied professions, so that there was no distinction between professionals and amateurs. Similarly many portrait painters took up photography as a profession, and exercised a noticeable influence on the style of photographic portraits and even of landscape photographs.

In the first few years studios were few in number, but the introduction of the negative process led to a rapid increase. Methods were improved and in 1860 the technique of negative retouching was introduced by the photographer Rabending and became widely practised. Amongst prominent professionals in the period up to the turn of the century the following are worthy of mention: Ludwig Angerer, Viktor Angerer, Hermann Vogel, Fritz Luckhardt and Perlmutter.

In 1905 the Photographengenossenschaft (Photographers' Association) was formed in Vienna, the Reichsverband der Photographengenossenschaften (National Union of Photographers' Associations) followed in 1906, and in 1908 a school for photographic apprentices was opened in Vienna by the Photographengenossenschaft.

Today all Austrian professional photographers must belong to the Photographeninnung (Photographers' Guild) of the federal province where they practise their profession. All provincial guilds are affiliated to the central Bundesinnung (Federal Guild). These guilds support the economic and professional interests of their members and are also responsible for professional training.

Amateur Photography. The first organization of amateur photographers to be formed in German-speaking territory was the Club der Wiener Amateurphotographen (Vienna Amateur Photographic Club) which dates from 1887. It later changed its name to Kamera Klub. The Wiener Photo Club (Vienna Photo Club) was formed in 1897, the Club der Amateurphotographen (Amateur Photographic Club) in 1903. In 1911 the Wiener Lichtbildner-Club (Vienna Photographic Club) was formed from the earlier Gesellschaft für Photographische Kunst (Society for Photographic Art). Many more clubs came into being, in particular a large number of photographic sections of the Naturfreunde (Naturalists) touring club, which popularized photography among hikers and mountain-climbers. Today the majority of Austrian amateur photographic clubs are affiliated to the Verband Österreichischer Amateur-Photographen-Vereine (Association of Austrian Amateur Photographic Clubs). In 1948 Austria became a member of the Fédération Internationale de l'Art Photographique (F.I.A.P.)

Among the workers who have had an important influence on the progress of photography in Austria the following are particularly worthy of mention: Dr. Hugo Henneberg, Dr. Friedrich Spitzer, Hans Watzek, Heinrich Kühn, and the late Rudolf Koppitz, of the Graphische Lehr- und Versuchsanstalt. Kühn was responsible for the special Imagon lens, which was manufactured by Rodenstock to his specification.

Over the years many different trends have of course manifested themselves in Austrian photography. Today's workers may be said to be pursuing a middle course; they are not exclusively wedded to modernism, nor have they remained rooted in the methods of the past. They try instead to maintain a balance between the traditional and the modern approach.

Periodicals. Apart from the *Photographische Korrespondenz* (Photographic Review) already mentioned, there are the *Allgemeine Photographische Zeitung* (official publication of the Photographers' Guild), and *Photo-Wirtschaft* (trade publication).

Amateurs are served by *Galerie* (formerly *Photo-Digest*), the official publication of the Verband Österreichischer Amateur-Photographen-Vereine, mentioned above. There is also a photographic art magazine which has been published since 1950 under the title *Österreichische Photo-Zeitung* (Austrian Photo Journal).

AUTOCHROME PROCESS. The first practical system of colour photography, invented 1903 by Auguste and Louis Lumière, who introduced, in 1907, Autochrome plates, manufactured by their firm at Lyons. A colour "screen" was formed by coating a mixture of starch grains dyed in the primary colours on to a glass plate. A panchromatic emulsion layer was exposed and, after reversal development, viewed through the same "screen".

See also: *Colour synthesis.*

AUTOCORRELATION FUNCTION. Mathematical function which provides a complete statistical measure of the physical (as opposed to visual) effects of granularity. By so correlating the fluctuations in density due to granularity at any point of an image with the fluctuations at all other points, both the size of the fluctuations and their distribution over the image surface can be statistically represented by a single function.

See also: *Information in the image.*

AUTOMATIC EXPOSURE CONTROL. System of exposure setting in cameras and other photographic gear, where the action of light on a photo cell system directly controls the amount of exposure of the sensitive material without manual interference. In still cameras automatic exposure control systems may consist of an iris diaphragm or a shutter setting mechanism directly linked to a built-in photoelectric meter. Sometimes the current of the meter circuit directly controls the period during which the shutter remains open. In enlargers an automatic control system generally uses a photo cell to control the enlarger illumination.

See also: *Enlarging; Exposure automation.*

AUTOMATIC FOCUSING. Term generally applied to focusing devices incorporated in cameras by which the act of sighting the subject through a rangefinder automatically brings the lens into focus on the subject. On enlargers it means that the lens is automatically kept focused on the easel while the head of the enlarger is raised or lowered. True automatic focusing is the means by which an independent mechanism keeps the lens focused on a given subject.

See also: *Focusing (automatic).*

AUTORADIOGRAPHY. Photographic method for recording the distribution and location of radioactive material within a specimen. The basis of this method is the placing of a sample (such as a plant leaf or a histological section containing radioactive material) in contact with a suitable photographic emulsion. After exposure and processing, the photographic layer reveals the location of the radioactive material within the sample. The image thus obtained is called an autoradiograph.

The techniques may conveniently be divided into those applied to macro- and those applied to micro-autoradiography. The former concerns the recording of the distribution of radioactivity for example in the skin of a fish or in a sheet of metal. Microautoradiography is used in studying the location of radioactive material within a minute biological cell, where very high resolution is required.

Macro-autoradiography. A simple application of this method is the study of the distribution of radioactive material in a plant leaf. If a plant was nourished for some time with a solution containing radioactive phosphorus (P^{32}) this will be taken up by the plant stem and leaves. The plant is then placed in contact with a fast X-ray film for a few hours exposure, preferably in a vacuum cassette, in order to achieve intimate contact between the specimen and the film. The radioactive phosphorus decays with the emission of high-speed electrons, thus exposing the photographic layer and rendering the exposed areas developable. The result indicates the location and relative concentration of radioactive phosphorus within the plant as a whole or within the structure of a leaf.

Micro-autoradiography. Probably the most widely used method in micro-autoradiography is the stripping technique. Special autoradiographic stripping emulsions are now available, using a nuclear track type emulsion. The advantage of a stripped emulsion layer is that it can be brought in very intimate contact with the specimen, thus permitting high resolution, which is aided by the close packing of grains in a nuclear track type emulsion. Since a stripped layer of about 5 microns thickness is easily damaged and difficult to handle, it is reinforced e.g. by a 10-micron thick gelatine layer carried on a temporary glass support. The two layers can then be stripped off together. An area of the emulsion layer is cut out sufficient to cover a histological section on a microscope slide, with a margin at least ¼ in. all round. The slide bearing the specimen containing the radioactive material is then placed on the bottom of a glass dish filled with distilled water. The emulsion and its gelatine support are stripped from the glass plate and placed on the surface of the water with the emulsion side facing the specimen. As it swells for about 3–4 minutes, the emulsion-gelatine composite first crumples and then stretches out flat. It should then be lifted from the water by raising the slide underneath it. After drying the specimen with the superimposed emulsion layer, it is placed in a light-tight box for exposure, which may take a few days to several weeks, depending on the activity of the radioactive isotope and its half-life.

Processing is carried out with the emulsion layer in permanent contact with the specimen. The autoradiograph is then viewed under a microscope when superimposed on the specimen. This technique permits the accurate

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

alignment of the autoradiographic image with the microscopic details of the specimen. A resolution of the order of 1–2 microns can be achieved under most favourable geometrical conditions. The basic requirement that a thin sample should be brought into intimate contact with a thin emulsion layer, can also be met in other ways. These include mounting the sections directly on the emulsion layer, coating mounted sections with liquid emulsion, or dipping in the emulsion.

Applications. In biology, autoradiography has proved to be of great value in studies of the metabolism of plants and animals, also in investigations of the events occurring during mitosis and in the distribution of labelled atoms in chromosomes and in many other fields. More recently a new stimulus was given by the synthesis of a variety of organic compounds with radioactive hydrogen (H^3) which can be used in cellular investigations.

In engineering, autoradiography may be used as a tool for studies of lubrication problems, where the transfer of radio-active material from one surface to another can be examined. The degree of segregation of small amounts of foreign materials containing tracers, e.g. in steel may be studied or the uniformity of distribution of certain labelled atoms in a metal may be checked. Because of the cumulative action of the photographic layer, autoradiography is often preferable to the use of Geiger or scintillation counters, particularly if high resolution is required in the simultaneous recording of the distribution of radioactive material within several specimens. R.H.H.

See also: *Industrial radiography; Medical radiography; Nuclear physics; X-ray film.*

AUTOTRANSFORMER. Transformer in which the primary and secondary windings are formed by tapping one continuous winding at suitable points. The transformation ratio is the inverse of the ratio between the turns of wire around the whole winding and the turns on the tapped section.

See also: *Transformer.*

AUXILIARY LENS. Simple lens placed in front of the camera lens to change its focal length. Usually called a supplementary lens.

AVAILABLE LIGHT. Loosely applied term intended to describe photography in poor lighting conditions without supplementary illumination.

AWARDS. Most national photographic societies and associated organizations make awards for merit in their various fields of activity—in addition to the traditional medals for exhibition successes. These awards may take the form of medals, cash, or kind and are provided either out of the Society's funds or from the interest on money bequeathed for the purpose. The list of awards below is a selection of most of the more important ones.

America. The following are the principal photographic awards made in America by the leading societies.

Principal awards made by the Photographic Society of America include:

Progress Medal: bronze medal awarded annually, if a suitable nominee is forthcoming, for an outstanding contribution to photography or an allied subject.

P.S.A. Service Medal: awarded for the encouragement of work for the Society and photography.

Journal Award: awarded for the best scientific or technical paper published originally in an official publication of the P.S.A.

Awards made by the Society of Motion Picture and Television Engineers include:

Progress Medal: gold medal awarded annually, if a suitable nominee is forthcoming, in recognition of a significant contribution to the advance and development of motion picture technology.

Samuel L. Warner Memorial Award: made for outstanding contributions in the field of recorded sound on motion picture films.

Herbert T. Kalmus Award: gold medal for major contributions to the scientific progress of colour in motion pictures.

David Sarnoff Medal: gold medal awarded for an outstanding technical contribution in the field of television.

Journal Award: awarded for the most outstanding paper originally published in the Journal of the Society the preceding year.

The Society of Photographic Engineers makes the following award:

Progress Award: silver medal awarded for achievements in the advancement of the science of photography.

The National Press Photographers Association makes the following awards:

Joseph A. Sprague Memorial Award: bronze plaque and scroll and up to three gold rings presented in the course of a year to outstanding press photographers.

The Photographers' Association of America makes the following award:

George Harris Award: sculptured medal presented annually to the professional photographer who has achieved most for his profession during the preceding year.

Specialized awards are also made by the American Society of Photogrammetry and the Biological Photographic Association, while a number of other organizations also grant honours or degrees.

Australia. Awards of medals and plaques are made by the Australian Photographic Society.

Austria. The Wiener Photographische Gesellschaft (Photographic Society of Vienna) makes the following awards:

Society Medals: gold, silver and bronze medals awarded to suitable persons of any

nationality for special services to, or achievements in, scientific and applied photography.

Voigtländer Medals: gold, silver and bronze medals awarded as above.

Society Diploma: awarded for photographic achievements and services irrespective of membership or of nationality.

Britain. In Great Britain the principal awards are made by the Royal Photographic Society:

Progress Medal: silver medal awarded annually, if a suitable candidate can be found, for some important contribution to the advancement of photography. It is one of the oldest and best-known photographic awards in the world.

Henderson Award: bronze medal and approximately £4 10s. in cash awarded annually for the best paper read or published on a photochemical subject.

Hood Medal: bronze plaque awarded annually for meritorious performance in some branch of photography.

Newman Memorial Award: bronze plaque awarded in conjunction with the British Kinematograph Society. Four plaques are awarded for outstanding work in cinematography.

Memorial Lecture Awards: medals, together with an honorarium, in each case awarded for lectures commissioned specially by the Lectures Committee. There are three: the Renwick (annually), Hurter and Driffield (bi-annually), and Trail Taylor (bi-annually).

Olaf Bloch Memorial Award: prize of books to the value of £10 awarded annually in conjunction with the Institute of British Photographers for the best essay on a set subject.

Williamson Research Award: grant in cash or kind awarded annually for research directed to the solution of one or more technical problems connected with photography.

France. The following awards are made by the Société Française de Photographie (Photographic Society of France):

Davanne Medal: bronze medal awarded annually for any notable improvement in photography.

Janssen Medal: bronze medal awarded every other year for some outstanding service to photography.

Peligot Medal: bronze medal awarded as with the Janssen Medal every other year.

Germany. The following award is made by the Gesellschaft Deutscher Lichtbildner (Society of German Photographers):

David Octavius Hill Medal: gold medal awarded from time to time to outstanding personalities of any nationality who have contributed notably to progress in photographic research, manufacture or practice.

The Deutsche Gesellschaft für Photographie (German Photographic Society), have awarded an annual Kulturpreis (cultural award) since 1959 consisting of DM 10,000 and a lens symbol mounted in gold.

The West German Government has awarded, since 1961, a unique annual Youth Photo Prize, to the value of D.M. 10,000.

The Deutsche Kinotechnische Gesellschaft (German Cine Technical Society) make one important cine award:

OskarMesster Medal: bronze medal awarded for outstanding contributions to cinematography.

Holland. The Dutch Society of Press Photographers awards cash prizes for the best exhibits at its World Press Contest.

Sweden. Scholarships are awarded by the Sweden-America Foundation for study in the United States; by the Swedish Photographers' Association; by the Stockholm municipal authorities, and by many publishing houses. In addition there is the following:

Svenska Dagbladet Award: gold medal and money prize for the year's best photography. It is presented annually by, and named after, Sweden's leading newspaper.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

B

BABIES. To the parents, the pictures of a baby provide a permanent record of the child's development. In the first few months babies are changing almost daily, and the camera is the only way of capturing the fleeting phases.

Technique. From the photographer's point of view, the main problem of baby photography is the smallness of the subject. The bodies of very young babies are unattractive, so the camera must confine itself to the facial features and expression. This means either getting close, or using a long focus lens, according to the type of camera. If the camera cannot be focused for close-ups, the difficulty can be overcome by using a supplementary lens.

Working close to the subject means that the photographer must avoid parallax errors unless he is using a single lens reflex camera or one with automatic parallax compensation. Then the closer the subject, the shallower the depth of field, so that it becomes more difficult—and more important—to focus accurately. A miniature camera will give the required depth of field at quite wide apertures, but with the popular roll film types it will be necessary to stop down to as little as *f* 11. With such small apertures, the correct exposure is often too long to arrest movement unless the fastest available panchromatic film is used. The minimum exposure for small babies, unless they are asleep, is 1/50th second, and shorter still for bigger—and livelier—children.

Perspective distortion is also apt to be a nuisance at short distances, and the baby's arms and legs must not be allowed to point towards the camera. The baby's eyes are always the best points to focus on—whatever else is blurred, the eyes must be sharp.

Subject. As a baby cannot understand what the photographer wants, it cannot be expected to co-operate, nor can it be threatened or forced. The only answer is to be patient until the right moment comes naturally. In any case the baby's mother or someone responsible must always be present. Even if the photographer is on the best of terms with his subject, he will be much too occupied in taking the photograph to act if the baby is in danger of rolling off the table or hurting itself in any other way.

Babies live according to a very strict routine and if it is upset, it makes them unhappy. Also, small babies tire quickly and sessions must be very brief. So the work must go quickly and smoothly. Everything possible must be prepared before the baby is brought into the room. Lights and background should be set up, camera loaded, exposure measured. This leaves the photographer free to watch for the right expression. When it comes, it never lasts more than a fleeting second, and a last-minute change in lighting arrangements or exposure may mean missing a brilliant picture.

BABIES INDOORS. For indoor daylight shots, the window should be to one side of or even somewhat behind, the baby. Use a reflector to light the shadow side.

Lighting. For indoor pictures, two Photofloods on the subject are sufficient for most occasions, and as they give off a good deal of heat, the baby must be dressed lightly or not at all. It is a good plan to light the background separately, choosing a plain wall or other neutral surface for the purpose.

Flashlight can be a most convenient means of photographing baby. Even the small bulbs, or the smaller electronic sets, are powerful enough to permit the use of a small stop. This will give the necessary depth of field at close

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

BABIES BY ARTIFICIAL LIGHT. The main light shines down on the baby, a fill-in lamp near the camera lights up the shadows, and a third lamp illuminates the background.

distances. The general principles of lighting apply to flash too, i.e., to obtain any modelling in the subject, do not use the light source close to the camera. As the camera and flash will be rather close to the baby it will often be sufficient to put the flashlight at a distance of one foot from the lens. This distance should be increased when taking the picture from farther away.

With one bulb only, put the baby near the background so that this will also get some of the light. A second flash put behind the baby and directed on the background can be very effective.

Flash bulbs are usually coated with a safety lacquer, but there is a very slight chance that they might explode on firing. Always have a safety screen in front of the bulb when photographing babies.

Good pictures may also be taken near or in a window by daylight or in sunshine. In this case, since there are no clouds to act as reflectors and light up the shadows, a white sheet or card should be held up as a reflector just clear of the picture area to soften the contrast.

When taking pictures out of doors, side—or even back—light gives the best modelling. Here, too, a reflector will improve the picture greatly. The baby's eyes will take more kindly to the light from the reflector than to direct sunlight and will look larger and more expressive in consequence.

BABIES OUTDOORS. Keep the sun to one side or behind the baby to prevent the infant from screwing up its eyes. Use a reflector to provide fill-in light in the shadows.

The First Weeks. Most of the routine of the baby's day will make good pictures. The first few weeks are mostly spent in sleeping and feeding, and the baby can be photographed asleep, or in the arms of its mother. The periods of wakefulness at this age are short, so the photographer must work fast. The baby's body does not photograph well in the early weeks, and bathing pictures are best left until later, or at least taken only for record purposes.

The Third Month. In the third month the first really lively pictures become possible. The baby uses its hands much more; it discovers things by touch, plays with its fingers or the blanket, and smiles when talked to. Best of all for the photographer, it begins to raise its head when laid face down. This pose must not be overdone, however, and care must be taken to see that the baby's arms are tucked under its chest to support it.

The Fourth Month. As the baby gets older the possibilities for pictures multiply. At four months it can hold up its head without difficulty when lying face down; it reaches for toys, and reacts to faint sounds. By this time it looks attractive without its clothes, and since it loves playing in the bath, that is the place to photograph it at its best. A high viewpoint—e.g., standing on a chair by the bath—will give the photographer the best shots, but he must work quickly and have everything ready as the time is strictly limited.

The Fifth Month. At this age the baby begins to hold and chew things—a rusk or a bit of banana—and it will hold other objects in its hand. It can now be propped against cushions and photographed, and there is ample scope for similar pictures on the floor, and in the pram or playpen.

Later. From eight months the baby begins to crawl and must be kept still by giving it a toy to occupy its attention, or have its movements restricted in some way—e.g., by sitting it in a high chair. After eleven months it begins to feed itself and may be photographed holding a cup or spoon. There are many possibilities here, but messy foods like chocolate or spinach should be reserved for special effects.

From this date its development makes rapid progress, and the opportunities for making pictures increase as it learns first to kneel, then to stand, and finally to toddle. There are endless pictures to be made of its playful moments, its moods, and the regular events of its daily life, and the more automatic the photographer can make his technique, the more of the really significant instants he will be free to observe and capture. W.S.

See also: *Children; Flash technique; Portraiture at home; Portraiture outdoors.*

BACK FOCUS. Actual distance that separates the vertex of the back surface of the lens and the film when the lens is focused on infinity. May be greater or less than the focal length.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

BACKGROUND

The background of a photograph should be selected and handled with the same care as the subject. Some photographs have no background—e.g., a landscape or part of a subject taken close up—but a great number consist of a single object or a group of objects seen against a background—e.g., portraits, figure studies and articles of all sorts. In all such cases the background must be thought about; it is easy to ignore or forget about it when making the exposure but it is impossible to overlook it in the print.

Generally speaking, the background should be unobtrusive—i.e., even in tone, without any sharp contrasts and softly defined or even blurred. It should be either lighter or darker than the parts of the subject against which it is viewed. The background of the finished print may consist of: the normal setting of the subject (as with most fixed subjects), a chosen natural artificial background. F.P.

History. The idea of using backgrounds of painted landscapes and interiors to enliven daguerreotype portraits was patented by Antoine Claudet in December 1841, but they were little used in England. After carte-de-visite portraits became fashionable in 1859, the photographer's studio became a stage full of properties and pictorial backgrounds. The classical column and curtain drawn back to reveal a landscape, which had served portrait painters, were pressed into service. Camille Silvy frequently designed painted backgrounds specially to indicate the status of a well-known sitter. In general, the humbler the sitter's home surroundings, the greater his desire for splendour; therefore the grander the studio, the more business the photographer could expect. Marion & Co. of London, Smedley & Co. of Blackburn and Seavey of New York manufactured backgrounds and accessories to suit the clientèle of every photographer; e.g., military props for a garrison town, a ship's deck with mast and guns for a naval base. Alexander Bassano in London had a large variety of indoor and outdoor scenes suitable for all seasons painted on a roll 80 feet long. William Notman of Montreal arranged trees, rocks, tents and camp-fires in the studio, with stuffed deer and bears, so that the armed trappers waiting for their kill seemed genuinely on the trail. Salt made an excellent substitute for snow.

Each decade in the Carte and later Cabinet period had a specially characteristic accessory. In the 'sixties the balustrade, column and curtain; in the 'seventies the rustic bridge and stile; in the 'eighties the hammock, swing, and railway carriage; in the 'nineties palm-trees, cockatoos, and bicycles; and in the early twentieth century, a motorcar for snobs.

Architectural and garden backgrounds have remained a favourite with society photographers, but in general most leading portrait photographers have always used plain backgrounds, which do not distract attention from the sitter's personality. H. & A.G.

The Normal Setting. The background of a fixed subject—like a tree, a statue, or a building—is largely out of the photographer's control, but much can be done to change the way the background finally appears.

(1) Suitably placed artificial lighting can be used to give the subject a darker or lighter background indoors (and even sometimes out of doors with flash). Out of doors the same thing may be possible by choosing a time of day when the sun is on either the subject or the background according to the tone contrast sought.

(2) By using a wide aperture and taking the camera up to the subject, the background can be thrown out of focus so that the subject stands out sharply by contrast.

(3) By shooting from a higher or lower viewpoint it is often possible to show the subject against a less "busy" background than by shooting at eye level.

(4) The background of a moving subject may be blurred while the subject remains sharp by swinging the camera as the exposure is made.

(5) Where the subject and background are of different colours, the tones can be separated by

BACKGROUND AND VIEWPOINT. A high camera angle emphasizes the background at the expense of the subject. A low-angle makes the subject stand out (often against the sky).

BACKGROUND TONE. A subject will stand out against a lighter or darker background, but tends to merge into surroundings of the same or reasonably similar tone.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

BACKGROUND SHARPNESS. The subject tends to get lost in a sharp background, but will be set off by an unsharp (e.g., out-of-focus) one. This may be achieved by differential focusing.

using a suitable contrast filter which deepens the tone of one and lightens the other.

(6) Where it is not practicable to apply any of the above expedients, an unsuitable background can always be dealt with by blocking out the background on the negative and substituting a new one by combination printing or retouching.

Natural Backgrounds. The sky, the sea, grassy banks, and stretches of sand are good natural backgrounds for outdoor pictures of people, animals, birds, and isolated landscape features, e.g., rocks, trees, motor cars, etc. All these backgrounds have the advantage of being fairly uniform in tone and texture, and the subject can generally be placed against them either by posing or, with fixed objects, by a suitable choice of viewpoint.

Masses of foliage and hedges are apt to be covered with distracting white spots in the print. This is because glossy leaf surfaces reflect spots of light, and the sun or the sky light often filters through in patches from behind.

Brick walls make suitable backgrounds for figure studies so long as they are far enough away from the subject to be thrown out of focus. The bricks take on a vague general texture that is not distracting. But the lighting on the wall and the subject should not be the same, and the wall should have no odd features. A broken brick or a patch of discoloration will pull the observer's attention away from any subject.

When the sky is used as a background for a portrait, the relative tones need careful handling. If the subject's face is sunburned, then the yellow filter that darkens the blue of the sky will lighten the sun tan. On the other hand, if the exposure is made without a filter, the tanned complexion will look unnaturally dark against a too-pale sky.

The solution varies with the relative tones of skin and sky and with the photographer's intention. Generally a green filter used with a pan film will give a natural rendering of tone values so long as the exposure is correct.

Artificial Backgrounds. The simplest artificial background is a length of cloth—a sheet, a roller blind, a curtain or even a carpet—hung from a rod or picture rail. As long as the material is stretched taut, this type of background will serve fairly well, but it is not ideal. Creases and folds can never be completely smoothed out, and they usually reproduce with an undesirable clarity.

For regular use it is better to use a rigid background of wall-board or plywood fastened to a frame, or failing that, a sheet of fabric stretched tightly across a rigid frame. A background of this type is known as a flat and is a standard item in the equipment of the commercial studio.

Backgrounds of this type can be made big enough for portraiture, but in larger sizes they are cumbersome. The most convenient large background is either a plain distempered wall, or a sized and painted sheet nailed on to two battens and rolled up when not in use.

An advantage of the rigid background is that it can be turned or tilted so that it appears darker or lighter than the subject.

Background Lighting Effects. Where possible, artificial backgrounds are coloured white or silver on one side and a neutral tint on the other. The light side is used for building up special background lighting effects.

By projecting controlled light on to the white side of the flat, it is possible to vary the tone of the background to blend or contrast with the tones of the subject, e.g., the face of the sitter may be contrasted against a dark area while the dark mass of the hair stands out against a light area.

By lighting the background with a spotlight and interposing suitable shapes in the beam, an abstract shadow pattern, or a suggestion of an actual scene can be created on the background to lend atmosphere to the subject. Artificial background effects created in this way are particularly appropriate for portraiture and nude studies.

Projected Backgrounds. Any desired scene which is available as a slide or transparency can be added by back projection on to a projection screen hung behind the subject. This is a favourite device of the motion picture studio but it is also used by commercial studios. It enables a model, photographed in the studio, to be shown in any desired surroundings without the trouble and expense of a trip to the actual scene.

With projected backgrounds, the subject lighting must be arranged so that it does not fall on the projection screen or it obliterates the background picture. It is also important for the direction and angle of the light on the subject to correspond with that in the projected scene.

The relative brightness of the projected background and of the foreground objects must also be matched to ensure that both are correctly exposed.

CC-0. Jangamwadi Math Collection. Digitized by eGangotri Digital Preservation Foundation, Chandigarh

Another method of obtaining a projected background is by front projection. This is more compact, since it eliminates the need for an extensive projection set-up behind the background screen. To avoid the projected image from interfering with the foreground objects, a special background screen and projection set-up is required. The special screen is a highly reflective and highly directional beaded screen which reflects virtually all light falling on it along the original light path. The projected image is therefore visible only within about 5° of the projection axis, but in this region is far more intense than it would be with a normal beaded screen. Any image projected on foreground objects is also invisible, since the scattering power of normal surfaces—dress fabrics, people and other objects—reduces the projected image brightness far below the lighting level of the foreground objects. For the same reason any spill light falling on the background from outside the projection axis has no effect on the brightness of the projected image.

To combine the projected background with the foreground object on the film, the camera must also photograph along the projection axis. This is achieved with a beam splitting arrangement using a semi-reflecting mirror or prism. The background is projected into the camera axis, and is reflected back along this axis, fusing perfectly with the foreground objects. Accordingly, no shadows are visible from the viewpoint of the lens. The camera, beam splitter and background projector are mounted together on a platform.

Background projectors for front projection can take black-and-white or colour slides of varying sizes, and the illumination is provided by either a high intensity projection lamp or by electronic flash. In one commercial outfit of this kind flash tubes up to 5,000 watt seconds are used, synchronized with the camera shutter and also with electronic flash units illuminating the foreground scene. Background image brightnesses obtained in this way can be adequate for exposures at *f*16 to *f*22 with a medium speed colour film, with a projected background size of 10 × 13 feet. The foreground scene is then lit to a lighting level to obtain the same exposures.

BACKGROUND BY FRONT PROJECTION. A, *special highly directional reflecting screen.* B, *foreground subject.* C, *lamps illuminating the foreground.* D, *semi-silvered reflector.* E *camera.* F, *projector.*

In addition to photographic images, transparencies of art work, drawn designs, and other graphic material can be used; this also provides a method for optical combination of foreground and background images in different scales (for example showing a model against an outsize perfume bottle for cosmetic advertisements, and so on). Subsidiary tungsten lamps in the projector and in the studio lighting set-up (modelling lights) permit preliminary setting up of the combined foreground and background composition.

Backgrounds are apt to call for more attention from the miniature camera worker than from users of larger types. This is because the greater depth of field of the miniature lens brings the background into sharp focus when the larger camera would blur it out of recognition. F.P.

BACKING. Special coating of dye, pigment, or paper applied to the back of the support of a plate or film to reduce halation.

See also: *Anti-halation backing.*

BACKLIGHTING. Lighting projected on to the subject from behind to produce a light fringe or halo so that the subject stands out distinctly from a darker background. It is also used to add sheen to hair and accent its soft texture.

As a lighting effect, the results can be very pictorial. But extra care in estimating the correct exposure is necessary.

See also: *Against the light; Lighting the subject.*

BACK PROJECTION. Projection of a picture on to the back of a translucent screen instead of on to the front of a reflecting one. This has the advantage that the projection apparatus may be behind the screen and therefore completely hidden and out of the way of the audience.

The method has been used for many years for showing slides and films in shop window displays, on exhibition stands, etc.; but it is finding increasing favour for home projection. It is also used to provide realistic background scenes for plays in television studios, as well as in commercial photography, where the model may be photographed in the required setting to save going on location.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

BACK PROJECTION SET-UP. The projector is arranged behind a translucent screen while the audience (or a studio set-up requiring a projected background) is in front. If space is limited, the projection beam can be reflected on to the screen with one or more mirrors arranged at suitable angles.

To economize on space behind the screen a short focus projector lens is normally used to keep the screen-to-projector distance to a minimum. A 45° mirror is necessary to reverse the picture from left to right, so that this introduces further economy since the projector is set up parallel to the screen; the beam is deflected on to the screen by the mirror and the space behind the screen requires to be only deep enough to accommodate this. Further mirrors can be used to zig-zag the beam and save even more space.

The screen may be thin fabric or matt surfaced glass or plastic. The modern black nylon screen is the most efficient since the picture brilliance is not affected by light falling upon it. This is essential in television and photographic studios where the bright floodlights would otherwise kill the background picture, and in the home it enables slides and films to be enjoyed in full room lighting. Daylight screens of this type, used for back projection, are also employed in visual aid education. H.H.

BACON, ROGER, 1214–94, English alchemist, philosopher and friar. A successful pioneer in experimental physics, was familiar with convex lenses and invented the magnifying glass. He knew the principle of the camera obscura from Arabian writings, but did not invent it. Explained the rainbow, perspective, and tides.

BAEKELAND, LEO HENDRIK, 1863–1944. American chemist (of Belgian descent). Invented the Bakelite plastic. Investigated silver chloride developable emulsions and produced the unwashed emulsion that gave the Velox paper and revolutionized the production of printing papers (1893). It is said that this discovery was anticipated by Eder and Pizzighelli. Biography by A. R. Mathis (Brussels, 1948).

BAIRD, JOHN LOGIE, 1888–1946, Scottish inventor of the first television system. Gave first demonstration, to members of the Royal Institution, January 1926, by reflecting light from an image on to a photo-electric cell. 1929, B.B.C. began experimental transmissions. April, 1932, Baird demonstrated ultra-short wave TV. 1937, B.B.C. decided to use the Marconi system.

BAIT. Pieces of food of a suitable nature placed to lure wild creatures into range of the camera; often fastened to a mechanical or electrical shutter release or synchronized flash so that the animal takes its own photograph.

BALANCE. The disposition of the various units making up a picture. When the size, lighting and position of the parts of the subject on one side of the picture are in a pleasing relation to those on the other, the picture is said to possess balance.

See also: *Composition*

BALANCES AND SCALES. Balances and scales in photography are used for weighing out chemicals when making up processing solutions.

Two types of balance are commonly used in photography: the spring balance and the chemical balance.

A spring balance consists of a weighing pan suspended from a spring associated with a scale and pointer so that a weight placed in the pan moves the pointer along the scale. The pointer indicates the weight directly on the scale. Such balances usually incorporate a zero adjustment. They are not very accurate for small quantities but are good enough for weighing down to about ½ oz. A convenient size for the photographer would weigh up to 1 lb.

Modern rough balances weighing down to 1 gram use the displacement of a weighted arm, similar to old-fashioned letterweights.

A chemical balance has two weighing pans suspended from a beam balanced on agate or knife edges. The whole balance either hangs from a hook, or is supported on a pillar. When weighing, the beam should swing to and fro during observation; when the pointer attached to it swings evenly in both directions, the two sides are accurately balanced. The accuracy of this type of balance is very high, especially with the laboratory type which is enclosed in a glass case to shut out air currents. Such balances can weigh accurately to 0·00001 gram. For photographic work, however, an accuracy of 0·01 gram is perfectly adequate; even an accuracy of 0·1 gram is often sufficient.

A set of scales has two weighing pans, mounted above a beam supported on knife edges. The material to be weighed is placed in one pan (generally a scoop or tray which can be lifted off), and has to be balanced by

CC-0. Adamjiram Digital Preservation Foundation

standard weights which are placed in the other pan. Often a small movable weight is mounted on the beam itself and slides along a graduated scale; this serves for weighing very small quantities. Scales can be made to measure small quantities accurately, but as the principle lends itself to a sturdy construction they are more often used for weights up to 14 lbs. with an accuracy of ½ to 1 oz.

Weighing with a Balance. For accurate weighing the pans and weights must be kept scrupulously clean. Chemicals must always be weighed on watch-glasses or at least on pieces of paper and not allowed to come into contact with the pans. The weight of the watch glass or paper is counterbalanced by a similar weight in the second pan.

Chemicals are always added or removed with a small spoon or something similar; they are never poured straight from the bottle or tin because a sudden rush of fine powder—e.g., amidol or metol—out of the bottle could swamp the pan and be difficult to clean up. For the same reason the pan should never be filled to capacity; it is safer to weight out large quantities in several lots.

Weights are usually housed in a small wooden box, with a pair of tweezers for handling. The smaller weights are best handled with the tweezers, so as not to soil them and so upset the accuracy.

TYPES OF BALANCE. Top: *Normal pair of scales mounted above a beam supported on knife edges. The parallelogram arrangement keeps the pans vertical.* Centre: *Hanging scales, with pans below the beam. The whole balance may be hung from a nail, or in the case of a chemical precision balance, fixed to a vertical pillar. In both instances the requisite weights go into one pan, the matter to be weighed out into the other.* Bottom: *Counterweight balance reading directly on a calibrated scale. The counter weight may be adjustable.*

System of Weights. Two systems of weights are in common use in Britain and the U.S.A.: avoirdupois and metric. Most photographic formulae give quantities in both systems, but the metric is more convenient, as it is easier to scale quantities down or up in the metric system than in avoirdupois.

A set of avoirdupois weights may consist of the following units: 4 ounces, two weights of 2 ounces, 1 ounce, ½ ounce, ¼ ounce, 60 grains, 40 grains, 30 grains, two of 20 grains, 10 grains, 5 grains, two of 2 grains, and 1 grain. This range covers anything from 1 grain to 10 ounces.

The most practical metric set may comprise: 100 grams, 50 grams, two of 20 grams, 10 grams, 5 grams, two of 2 grams, 1 gram, 0·5 gram, two of 0·2 gram, 0·1 gram, and 0·05 gram. This will weigh anything from 0·05 to over 200 grams. Specially accurate weights will go down to 0·005 gram, but these are hardly necessary in photography.

Coins as Weights. If no proper weights are available, British coins can be used as weights as follows:

Five shillingsworth of silver coins of any value	=	1	oz.
Half-crown	=	218	grains
Two-shilling piece	=	175	grains
Shilling	=	88	grains
Sixpence	=	44	grains
Silver threepence	=	22	grains
Three pennies or five half-pennies	=	1	oz.
Penny	=	145	grains
Halfpenny	=	88	grains

In some cases the coins of other countries are similarly related. L.A.M.

BALDUS, EDOUARD, 1820– (after) 1869. French architectural photographer born in Germany. Recorded historic monuments in Burgundy, the Dauphiné and Fontainebleau for the French Government, 1851. Founder member of Société Héliographique. Changed from the Calotype to the collodion process in 1854 and made for the Government a complete documentation of the new wing of the Louvre in over 1,500 detail photographs. Also noted for views, especially of mountains. Invented a photo-engraving process, 1854.

BALL AND SOCKET HEAD. Universal type of camera mounting made to screw on the top of a tripod.

See also: *Camera supports.*

BALLISTIC PHOTOGRAPHY. Photographic study of projectiles. Where these move at speeds in the region of 15,000 m.p.h., photography may provide the only means of investigating their characteristics in flight. These include velocity, aerodynamics—shape, behaviour and shock wave generation—and behaviour on impact.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

PHOTOGRAPHING SHELLS AND BULLETS. Top: *To measure the speed of a missile, a moving film camera is set up so that the image moves along a slit in front of the film while the latter travels across the slit.* A, *film.* B, *slit.* C, *lens.* D, *shell.* Centre: *The resultant picture is a curved smear* F, *equivalent to the time of travel through the distance* E. *The mean slope of this smear is also equivalent to the speed.* Bottom: *For a sharp picture of the shell in flight, the image must move across the slit in front of the film, while the latter advances in step with the image.* 1, 2, *and* 3 *are projections of the shell progressively recorded in the same relative positions on the film, building up a continuous and sharp picture.*

The first ballistic photographs (E. Mach, 1885/6) recorded moving bullets and shells in silhouette against the light of an electric spark.

The result was not a photograph in the generally accepted sense of the word (i.e., formed by a lens) but a record of the shadow of the projectile on the sensitized material. The short duration of the spark and its relatively great distance from the projectile and the sensitized material, combined to give a sharp image.

A similar technique is used today for the same purpose except that an electronic flash tube takes the place of the old open spark between metal electrodes. Photographs made in this way show the projectile as a sharp-edged black silhouette and may also show the pressure waves set up in the air by the passage of the projectile—(like the bow wave of a ship). This phenomenon, known as the schlieren (German for streaks) effect, is caused by the change in the refractive index of the air along the pressure wave and the consequent distortion of the rays of light before they reach the sensitized material. The number, shape and disposition of the waves provide an indication of the air resistance and stability of the projectile and so are important in designing for range and accuracy.

A high speed camera can record the projectile throughout its travel across the field of view. If the distance travelled across the field is known, this is represented by the width of the film frame; while the time of travel is indicated by the length of film on which the projectile's image appears, providing camera running speed has been accurately measured. So projectile velocity is equivalent to frame width divided by length of film. If ultra-short framing exposures are used, they will "freeze" the projectile's image, showing any erratic behaviour in flight.

The main requirement is therefore for good temporal and spatial resolution rather than pictoral accuracy, and for frame-by-frame analysis instead of "slow-motion" moving pictures. Still cameras, when used, generally have special ultra-fast shuttering devices or simple capping shutters for open flash work with short-duration and stroboscopic flash. High speed framing cameras and streak cameras are used more often, the former operating at rates between a few thousand and several million frames per second. The streak instruments may have writing speeds of over 250 feet per second.

For long-range missiles, widely spaced groups of cine theodolites record azimuth and elevation, so that the missiles' positions can be plotted by triangulation. More accurate still, are Schmidt multiple-exposure plate cameras, from which the position is deduced by reference to star images.

Conventional projectiles can be followed in much the same way by fast framing cameras covering fixed fields across the estimated trajectory. Flare or tracer indicators assist visibility, and fiducial marks in the cameras, and marker boards sited in the field of view, provide positional references. In this application, the ribbon frame camera, taking long narrow pictures across a 5½-ins. wide film, can cover a large section of the trajectory at once.

For closer work, velocity may typically be measured by a streak camera. This is aimed across the line of fire, with the optical slit parallel to the trajectory. The projectile is therefore recorded as a streak slanting across the film. Again, distance travelled is measured across the film and time along its length.

The streak camera can also give a pictorial image for aerodynamic study. For this it is mounted with the slit perpendicular to the trajectory and with the film moving in the same direction as the projectile's image. Having found the velocity, the film speed past the slit can be adjusted to match the calculated image

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

speed, resulting in a still picture of the projectile was taken from a moving free balloon. Since the course of the balloon cannot be predicted accurately, and it is not possible to repeat a run over the picture area, there is little point in such photography today. (The exception is the automatic photography of the earth from a stratosphere balloon from altitudes which cannot be reached by an aeroplane.) But a captive balloon or kite offers a vantage point that can be controlled within reasonable limits both in position and altitude.

by virtually orthodox moving film photography.

The same principle is applied in a multiple shadowgraph system, in which the projectile is fired through a tube having vertical slits at measured intervals along its length. Collimated light is projected on each slit through ports on the opposite side of the tube. From the slits, optical relays of equal length lead to a single streak camera, recording side-by-side images from the slits as the projectile passes each one. The distance apart between any two images along the film represents the time of flight between the corresponding slits, and hence the velocity.

A shell's behaviour on impact—say, with a sheet of armour plate—would normally be studied with a framing camera, photographing the sheet edge-on. Since the entire event might take less than a millisecond, electronic flash is the usual illuminant. It can be triggered by the shell piercing a metal foil or gauze screen in front of the armour plate and making an electrical contact between them.

Other forms of illumination for ballistic photography, apart from conventional sources, include spark gaps, argon bombs and rare gas discharge tubes. Complex circuitry is needed to ensure a square-wave output of constant intensity and, where necessary, rapid stroboscopic repetition. Where the flash duration determines exposure time, sparks can give exposures down to 1/1,000,000 second, while 1/100,000,000 second has been achieved with discharges through rare gases.

Synchronization, both of the camera with the projectile and of the projectile with the flash must be exact. Cameras need time to accelerate to high speeds, and electronic timing and frame-counting circuits may be required to programme starting the camera, opening the shutter, firing the gun and triggering the flash. The projectile itself can also initiate events, as already described, by connecting foil screens, cutting light beams or breaking wire circuits.

Since time is measured in distance along the film, it is usual to flash timing marks on the rebate, through an optical relay from an electronic timer. This compensates for any irregular running of the camera mechanism. P.B.M.

BALLOONS AND KITES. Most photographs that have to be taken from the air are best taken from an aeroplane, but there are occasions when it is more convenient to take them from a kite or captive balloon. The first really satisfactory aerial photograph, from a tethered balloon, was taken by J. W. Black in October 1860 from a height of 1,200 feet over Boston, U.S.A.

Nadar was the earliest photographer to work from a balloon in 1858, but most of his pictures

Kites. The pioneer of this field of aerial photography was a Belgian, A. Batut, who in 1887 took photographs of the ground with a camera attached to a kite. The exposure was timed by lighting a slow-burning fuse which released a stretched rubber band attached to the shutter control after the kite had reached the desired height.

At the beginning of the century, American meteorological observatories were using clockwork operated cameras, suspended below kites, for cloud photography.

The most stable kite for this type of photography is the Cody kite—a box-form kite divided into cells and made of reinforced silk, nylon or cotton panels stretched between bamboo spars. Any weight of equipment can be lifted by simply adding kites, one below the other on the same cable.

The photographic equipment is never attached directly to the first kite. This kite always acts as a pilot. It is launched first and when it is flying well clear of the ground—at least 150 to 200 feet—the next kite is attached. If the pilot kite will give all the lift required, the camera cradle is attached to the cable. The camera cradle is a small waterproof box with a window in the bottom through which the photographs are taken. The box is fitted with air stabilizing fins and a small drag parachute to prevent it from yawing and to keep it standing clear of the cable.

The camera with its clockwork automatic release and rewind mechanism is not loaded into the cradle until there is plenty of steady tension to ensure that it will be carried clear of the ground as soon as the cable is paid out.

Equipment of this type must be flown from a mobile power-operated winch—generally mounted on the back of a truck—because the cable tension may be several hundredweights. An amateur set-up is not difficult to contrive with two ordinary box kites flown one above the other to give stability, and a miniature camera.

The timed release is easy to arrange with either an alarm clock mechanism or the stretched rubber band and fuse mentioned above. In this case only one exposure can be made per flight.

But kites are not an ideal form of suspension for delicate photographic equipment. They are apt to yaw violently from side to side, or fall to the ground when the wind drops.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

CAMERA KITE. The camera unit is supported from the main cable holding the kite from the winch, and steadied by stabilizing fins and a small drag parachute.

Balloons. A much more satisfactory method is to fly the camera from a balloon on a still day. This was the method adopted in the American Civil War, the South African War and in World War I. In these wars the photographs were taken by observers from captive observation balloons. This function has now been taken over by the highly developed air force reconnaissance units.

Where photographs are to be taken from a balloon, it is no longer necessary to use a man-carrying type. The cost can be cut to a fraction by using a balloon just big enough to raise the camera and the required length of cable. If the pictures have to be taken on days when the wind is more than about 5 m.p.h. spherical balloons are useless and a properly stabilized balloon flown from a winch must be used.

By operating only when the wind is light it is possible to get good pictures using one or more spherical rubber balloons like the type used in meteorological offices. If the balloon is filled with ordinary coal gas from the domestic supply, every 1,000 cubic feet will lift roughly 50 pounds of gear, including the weight of the envelope and flying wire or cord.

The camera with its release gear is housed in a box as for kite photography (above) and the box is fitted with an aerodynamic stabilizer and a small drag parachute or drogue. This unit is attached to a suspension wire or cord long enough to let the balloon be flown well clear of the ground before it is added.

When the unit leaves the ground, the slight wind drag on the drogue swings it away from the flying wire so that the wire does not appear in the picture.

The layer of atmosphere near the earth prevents photography of optimum quality of heavenly bodies from the earth. Scientists are constantly working to find ways of getting astronomical telescopes and cameras into the clearer upper layers of the atmosphere. One of the most successful methods to date is to sling the apparatus below a high-altitude free balloon. By using a small amount of hydrogen or helium in a giant envelope of extremely light plastic sheet, photographic gear and telescopes up to 36 ins. have been raised to over 100,000 feet to take photographs of the planets. When the balloon reaches its ceiling, the gas inside fills out the plastic envelope. In time the pressure builds up and the balloon bursts. The envelope is designed so that after bursting it forms a parachute which lowers the apparatus gently to the ground. Photographs taken in this way show details which were previously beyond the scope of the finest telescopes. Both polythene and foil material balloons are used today for such high altitude work.

Camera. A camera with a normal angle lens will cover a square of ground approximately 70 × 70 feet when looking down from an altitude of 100 feet. The area covered at any other height is given by

Side of Square Covered
= Height of Camera from Ground × ·706

In aerial photography from kites or balloons, the camera should be at least 50 feet from the ground to keep it out of the worst of the ground wind eddies. The air is always turbulent in the lee of trees and tall buildings.

The shutter speed for such photographs should be at least 1/100 second to allow for the constant movement of the camera.

When taking single shots, it saves time to make the shutter release gear operate a visible indicator, e.g., make it unroll an orange-coloured streamer. This provides a warning that the exposure has been made and that it is time to haul down and reset the mechanism.

From all points of view, short of using a specially designed camera, a 35 mm. precision miniature is the best camera for this work; it is small, light, and easy to couple to an automatic exposure mechanism.

Negative Material. Medium speed panchromatic plates or films generally give the best results; they allow for enlargement of sections of the negative without unpleasant graininess. A pale yellow filter counteracts any ground haze and brightens up the tones of grass and foliage.

Uses. This photographic technique—with balloons especially—is particularly suitable for such enterprises as archaeological expeditions, site excavation, and prospecting; the equipment is cheap and self-contained and it is capable of yielding detailed plan views of relatively small areas of terrain without the difficulty or expense that would be involved in commissioning an aircraft. F.P.

BANQUETS. The work of the professional photographer at banquets, dinners and similar functions falls into two main headings; he may be called upon to take formal groups showing all the assembled diners, as well as a series of informal, intimate close-ups of individual parties seated at their tables.

The formal group, properly taken, can make a very impressive picture. It is not a difficult

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

photograph to take provided that the correct technique is adopted and full use made of the normal room lighting. The exposure is always based on a brief time exposure of a duration of 1–5 seconds, according to the intensity of the lighting. Many of the large banqueting halls have their lighting installation overhauled and cleaned during the summer months, in time for the season. As the installations collect a certain amount of dust, the regular banquet photographer will find it necessary to increase his exposures slightly, as the season progresses. The basic exposure. is usually supplemented by exposing a flash bulb of medium power to add brilliance to the foreground.

If the photographer ignored the natural lighting and made use only of a high-intensity flash he would produce a negative that would be almost unprintable. The picture would be grossly over-exposed in the foreground, and the far distance would be just as seriously under-exposed.

Professional photographers normally use half-plate or whole-plate cameras for this work in conjunction with short-focus or even wide-angle lenses. There are obvious disadvantages in making use of such lenses for there is always some distortion at the edges of the picture, but conditions rarely permit the photographer to use a lens of normal focal length.

Technique. A tall, rigid tripod is an essential. Its weight will depend on the camera. Firms who specialize in such work use a 6-foot step-ladder modified to accommodate the camera on the top platform. Failing such aids, it is usual to work from the stage, the band platform, or (best of all) from a balcony of medium height. The camera must be able to look down on the assembly if everyone is to be seen clearly in the finished photograph.

It is standard practice to work obliquely across the lines of tables. When the camera looks directly down the length of a table it is usually impossible to see more than a few of the guests near the front.

BANQUET GROUPS. If the camera covers the assembly from one corner, guests do not obscure each other. Diners at ends of tables are moved to stand at edge of group.

As the principal guests are normally seated at the top table it is usual to ask them to stand throughout the exposure. It is also customary to take the photograph as soon as the guests have taken their seats after the saying of Grace. Later in the meal the tables become disarranged and the scene is never free from the presence of hurrying waiters. Furthermore, trouble is likely to be experienced with haze from cigarette smoke, particularly if the room is very long and if many guests have taken the opportunity to smoke.

The necessary over-all sharpness is achieved by focusing the camera on a point about a third of the way down the tables and then stopping down to *f* 16. Electronic flash, being fast, easy to use and portable, is popular for photographing dancing, floor shows, etc. Using fastest panchromatic material in a normally well-lit room at this aperture, a time exposure of 4 seconds should be ample to produce a negative of fairly even over-all density. The slight falling off in illumination in the foreground is rectified by firing a medium power flash bulb just before closing the shutter.

Subject. The great secret of success in this field of photography is a knowledge of "audience-control." The photographer must make certain that everyone present knows that a photograph is about to be taken and that they realize that they have to keep absolutely still throughout the exposure. This information is conveyed either by the photographer (who must speak slowly, clearly and compellingly) or, at larger functions, by the toastmaster to whom the photographer has previously explained what is wanted.

Examination of the subsequent prints shows unmistakably how far the operator has succeeded in controlling his audience.

The intimate type of picture can be taken with the aid of small flash bulbs or more often nowadays with an electronic flash. It is usual to pose these small groups to be sure of getting pleasing expressions and to avoid catching someone while eating. If poor lighting conditions should make a small aperture impracticable, good overall sharpness can be achieved at a wider aperture by using the front-tilt on the camera.

The Business Side. The business side of banquet photography is normally conducted on "high-pressure" lines. If possible, the photographer circulates proofs of all pictures among the guests before they leave so that he can take orders on the spot. Successful exponents of such methods make a point of adding sufficient to their charges to enable the finished prints to be posted to customers with secure wrapping to protect them. G. Cg.

Books: *Group Photography*, by Gordon Catling (London).

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

BARIUM SULPHATE. Used to prepare baryta paper on which most photographic printing papers are coated. As barium sulphate is opaque to X-rays, it is largely used in radiography when it is administered to patients either orally or by injection. This enables the operator to "see" the shape and position of organs which, without this aid, would not be recorded.

Formula and molecular weight: $BaSO_4$; 233.
Characteristics: A heavy white powder.
Solubility: Insoluble in water and alcohol.

BARNACK, OSKAR, 1879–1936. German camera designer. Joined the firm of Ernst Leitz in 1911 as mechanic in the experimental workshop. Made a small roll-film camera for trial exposures of cine film employing double standard 35 mm. frame size (24 × 36 mm.) and so in 1914 produced the Leica prototype. The first series of six Leicas appeared in 1924.

BARN DOORS. Colloquial term for the flaps placed in front of a spotlight to control the spread of the light. The flaps are hinged so that they can be adjusted as required. Barn doors are sometimes necessary when only part of a subject is to be illuminated.

BARREL DISTORTION. Type of distortion of the image formed by an insufficiently corrected lens, where magnification decreases with increasing obliqueness of the image-forming rays. Lines parallel with the picture edge appear to bend inwards near the corners crowding in more subject area on a reduced scale.

See also: *Aberrations of lenses.*

BARYTA COATING. Base of the photographic image in most types of printing paper. It consists of an emulsion of barium sulphate in gelatin, spread in a thin film over the paper backing and subsequently coated with the sensitive emulsion. Its main purpose is to provide a smooth white chemically inert base.

See also: *Supports for emulsions.*

BASE. In photography, the support on which a sensitized emulsion is coated—e.g., the glass of a negative, or the paper of a print—is called the base.

In chemistry, a base is a metallic or metalloid (e.g., ammonium) oxide or hydroxide which combines with acids to form salts; a base that is soluble in water is an alkali.

See also: *Supports for emulsions.*

BASKETT'S REDUCER. Physical reducer for negatives, which works by removing the silver deposit by abrasion. The original Baskett's formula consisted of equal parts of terebene, salad oil and metal polish. Any similar mixture of an abrasive metal polish and oil or vaseline will do.

See also: *Reducing.*

BAS-RELIEFS. Carvings, sculptures or other forms of images in low relief. In photographing them strong oblique lighting is usually required to obtain sufficient modelling.

Double Image Method. Prints resembling photographs of bas-reliefs can be made from negatives of normal subjects. The method is to make a transparency from the negative by contact printing on to a lantern plate or similar material. The negative and positive are then placed together in the enlarger slightly out of register, and a print made in the normal way. The result is a picture with the main outlines indicated by dark or light contours, and with somewhat distorted over-all tonal gradation. Both the negative and positive should be rather soft for the best results.

This technique has also been used to obtain strong pictures of actual bas-reliefs having very shallow modelling, such as old and worn coins. In this case only the slightest displacement of negative and positive is called for—sufficient to accentuate the characters of an inscription, for instance, without giving a double image.

The direction of displacement should coincide with the direction of the lighting on the subject so as to accentuate the natural shadows and highlights.

Swelled Gelatin Method. If a light sensitive layer of bichromated gelatin is exposed under a negative, the emulsion under the shadow areas is hardened by the actinic rays but that under the highlights remains unaffected.

The unaffected gelatin absorbs relatively large quantities of water and swells up while the hardened areas absorb little water and so do not swell as much. The result is an image in relief in which the highlights stand out and the shadows are depressed. This image may be cast in plaster while still wet, or if it is gently heated to just below melting point it will persist in the dried emulsion. Either way it is possible to obtain relief facsimiles from it in plaster or metal. Correctly carried out the method yields relief comparable to that of coins or medallions.

This method was developed by Carlo Baer, who constructed a special lighting arrangement for the purpose. The object of the arrangement was to illuminate the subject (invariably a portrait) in such a way that the resulting densities in the final negative varied according to the physical relief of the surface photographed and not the normal effects of light, shade and colour.

If the method is attempted without some such arrangement it is essential to treat the subject to remove colour contrasts—i.e., by powdering the hair and face—and to light it evenly from each side to give symmetrical modelling. Finally, the negative may need considerable local intensification and working up to give the necessary strong contrasts.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The plate on which the negative is printed can be prepared by coating glass with the following mixture:—

Gelatin	2 ounces	50 grams
Water	7 ounces	175 c.cm.

Leave the gelatin to soak for 4 hours and then heat on a water bath until dissolved; stir in 120 minims (6·5 c.cm.) of glycerin, strain, and coat on to glass plates while still warm. The above quantity is enough to coat 40 square cm. (6·5 square ins.).

At any time after drying, the plates may be sensitized by bathing for 15 minutes in a 6 per cent solution of ammonium bichromate and drying in darkness.

The plate is contact printed by daylight to give a good strong image, and then soaked in water until the gelatin swells to form the relief.

The swelled gelatin method is only suitable for producing reliefs of well defined objects and for portraits; it is useless for landscapes. As the amount of relief is small, the finished bas-relief should not be more than 3 ins. or so high, or the effect will be lost. F.P.

See also: *Photosculpture ,Tricks and effects.*

BATCH NUMBERS. Serial numbers stamped by the manufacturer on all packages of sensitized materials coated from a particular batch of emulsion. While variations between one batch of emulsion and the next are never very great, they may be serious enough to affect exposure and contrast, particularly where large quantities of the material are being exposed and processed to a rigid technique—e.g., in photo agencies, photofinishing and picture postcard manufacture.

Where variations in speed from one batch to another might be costly, the user keeps a check on the batch numbers of the materials as they come from the supplier. When the batch number changes, a test run is made with the new material to see whether any change is necessary in the technique standardized for the previous batch. This is particularly important with colour materials, which have a more limited exposure latitude. Colour render- to batch, and where constant quality is required in a large number of exposures, all the material should come from the same manufacturer's batch.

See also: *Keeping qualities of materials.*

BATTERIES

In recent years there have been spectacular improvements in portable batteries, and many items of photographic equipment can now be run off small built-in batteries. These can power film transport motors in cine and still cameras, solenoid-operated remote shutter controls, motor-driven focusing mechanisms and portable tape recorders. Batteries are also used for firing expendable flash bulbs and operating electronic flash units, for the comparison lamp in certain kinds of exposure meter, and for the projector lamp in some low voltage slide projectors.

Though there are many battery types, a photographer with battery-operated equipment can usually be sure of getting an identical size and type of replacement when a battery runs down. However, there may be emergencies when he may have to use or adapt an alternative type. In addition, the prices of the different types vary widely for what often appears to be the same specification.

Practical Aspects. Strictly speaking a distinction must be made between electric cells and batteries. A cell is the basic current-generating unit. A battery is an arrangement of two or more cells connected in series to provide increased voltage, or in parallel to provide increased current. The cells may be sold already connected as a battery in a common case, or they may be sold as single units which can be made up into a battery of any required multiple of the voltage of the basic cell.

The important properties of a cell are:

Shelf Life. How long will it stay good in store?

Discharge Characteristics. How does it hold its voltage under loads of all kinds: normal, light heavy, continuous, intermittent and at temperatures above and below normal?

Capacity. How much energy will it deliver before the voltage drops below the lowest acceptable level?

Economics. How much does it cost both in actual cash and in relation to the service it gives?

In addition to the electrical characteristics, there are the physical characteristics to be thought of—size, weight and the risk of damage to equipment by corrosive liquids or gases given off by the cell in use.

The accompanying table compares these practical aspects over the range of cells suitable for photographic equipment. Generally it is safest to follow the makers' recommendation or, in their absence, to renew cells with others of the exact type. However, there may be exceptions to this rule as, for instance, when a piece of equipment is used under abnormal conditions.

What Kinds Are There? Cells can be divided into two broad categories: primary and secondary. Primary cells cannot be regenerated and have to be discarded when their voltage drops below the minimum working value. Secondary cells can be re-charged from an external power supply when they run down.

PRIMARY CELLS

The elementary form of primary cell consists of two electrodes immersed in a liquid electrolyte. The electrodes are most commonly carbon and zinc and the electrolyte may be an acid, an

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

alkali or a metal salt. Under these conditions there is a difference in electrical potential between the two electrodes and if they are joined by a conductor a current will flow from one to the other.

The voltage of the cell is always the same for electrodes of the same materials; increasing the size or area of the electrodes does not increase the voltage, but only the capacity of the cell. When a simple cell is under load a layer of ionized gas tends to build up on one electrode, raising the internal resistance and cutting down the output of the cell. For this reason the cell always contains a depolarizing chemical which disperses or absorbs the gas and helps to maintain performance.

There are five kinds of primary cell used in photographic equipment: simple carbon-zinc, leakproof carbon-zinc, layer type carbon-zinc, high energy alkaline manganese, and mercury.

Simple Carbon-Zinc Cells. These are the same small cylindrical cells that are used in ordinary torches. They are a development of the Le Clanché wet cell. The positive pole is a carbon rod surrounded by a mixture of powdered carbon and manganese dioxide. The negative pole is the cylindrical zinc case which is generally protected by a cardboard sleeve. The contents of the cell are impregnated with a jelly of ammonium chloride and sealed off with a layer of pitch. Cells of this simple type are cheap and reliable but they tend to swell near the end of their life—particularly if they are kept in a damp place—and may jam tight in the equipment. They may even burst and exude electrolyte which quickly corrodes and ruins metal parts. So they should always be looked at every month or so and never left in the equipment once they are run down.

Leakproof Carbon-Zinc Cells. These are a big improvement on the ordinary type and are well worth the small extra cost. The cell is enclosed in a sealed steel jacket and an internal air space above the electrolyte makes the normal gas vent unnecessary. This type of cell is safe to fit inside photographic equipment where leakage could cause costly damage. The voltage and other characteristics are the same as that of the ordinary carbon-zinc cell.

Both the ordinary and leakproof types are suitable for running small lamps, preferably on intermittent duties, and for operating capacitor flash units.

Layer Type Batteries. Compact high voltage batteries of carbon-zinc cells are made by assembling suitable numbers of thin-section layer-type cells. These consist of a flat sandwich of carbon and zinc with an electrolyte-impregnated card in between. When one cell in a high voltage assembly fails the entire battery has to be scrapped.

Layer-type batteries are frequently used in capacitor flash guns. They have also been employed to power electronic flash equipment but nowadays the high operating voltage is more conveniently obtained from a converter, which converts the low voltage direct current from an ordinary battery into direct or alternating current of the correct voltage for the equipment.

Alkaline Manganese Primary Cells. These look like leakproof carbon-zinc cells but use manganese dioxide in contact with the steel container as the positive pole and an alkaline electrolyte—usually potassium hydroxide. They have many advantages—low internal resistance, ability to supply heavy currents for long periods, good performance at low temperatures and a useful capacity of as much as ten times that of the comparable carbon-zinc cell.

Alkaline primary cells are excellent for driving the small motors of cine cameras and sound recording equipment, for electronic flash units and for running slide projectors. They give the same voltage as the ordinary carbon-zinc cell. Whether they cost more depends upon the type of use they get. Broadly speaking the alkaline cell works out cheaper on continuous heavy current duties and the carbon-zinc wins on long-term intermittent use at low currents.

Mercury Cells. Mercury cells use electrodes of zinc and mercuric oxide with potassium hydroxide as the electrolyte. In operation the mercuric oxide liberates mercury to form the positive electrode. It also acts as a self-depolarizer—i.e. it dissipates the film of ionized gas which tends to form on the positive electrode and slow down the action of the cell. So this type of cell can be discharged continuously for extremely long periods without its voltage falling off.

Weight for weight the mercury cell has six to seven times the capacity of an ordinary carbon-zinc cell, it is leakproof and its storage life is longer than that of any other primary cell. It costs more than other cells but may in certain circumstances be cheaper in operation.

Mercury cells are ideal for miniaturization. In the form of "button" cells they are fitted in photographic equipment where small size and weight are an advantage—e.g. built-in flash equipment, automatic camera mechanisms, and cadmium sulphide exposure meters.

SECONDARY CELLS

The secondary cell is rechargeable and is based on a reversible electro-chemical action. As in the primary cell, there are two electrodes immersed in an electrolyte. If an electric current is passed through the cell from an external source it produces a chemical change in the electrodes and charges the cell. If the electrodes are then connected to a load, a current will flow in the reverse direction from the charging current and the chemical state of the cell will go back to what it was before charging. This means that the cell can be used as a source of electricity that can be replenished when it runs down.

As it stores up electricity, a secondary cell

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

battery is also called an accumulator. In certain types of photographic equipment—e.g. where currents of the order of one or more amperes are required, a secondary battery, in spite of its higher cost, is a better proposition than a primary battery.

There are five kinds of secondary cell used in photographic equipment: lead-acid, nickel-iron alkaline, nickel-cadmium, silver-zinc and silver-cadmium.

Lead-Acid Accumulator. The commonest type of storage battery employs electrodes of lead and lead oxide in a dilute sulphuric acid electrolyte. During charging the cells give off gas, so they cannot be hermetically sealed. When lead-acid accumulators are fitted in portable photographic equipment they must be of the non-spill type which have filler plugs designed so that while they will allow gas to escape they retain the acid—even if the equipment is turned upside down.

Lead-acid batteries provide an efficient source of heavy currents. However, if they are left discharged the surfaces of the plates become coated with insoluble lead sulphate and the battery is ruined. Miniature lead-acid batteries are used in some electronic flash units and large, heavy duty types are used to drive camera motors and sound equipment used by professional film units working on location away from the mains.

The lead-acid accumulator requires regular maintenance. In addition to making sure that the accumulator is kept charged (the charge is gradually lost even during storage), this involves topping up the electrolyte with distilled water (never acid) which is used up in the course of the charge/discharge cycle.

Nickel-Iron Alkaline Batteries. This type of rechargeable battery employs electrodes of nickel and iron in an electrolyte of sodium hydroxide. Usually, the case of the cell is made of nickel-plated steel and forms one of the electrodes.

Nickel-iron batteries are extremely robust; they will stand heavy over-charging and short circuits and can also be left discharged for years without deteriorating. They need thus no maintenance. However, they have a lower voltage than the lead acid type and, for an equal amount of energy stored, they are bulkier, heavier and more expensive. For this reason they are not used in portable photographic equipment although they form a reliable power supply for outdoor filming operations.

Nickel-Cadmium Batteries. This type of battery

BATTERIES COMPARED

Cell	*Type**	*Working Voltage*	*Shelf Life*	*Special Characteristics*	*Best Suited for:*
Zinc-carbon	N	1·5	Fair	Low cost	Short term loads with intermittent use. Bulb flash equipment, hand torches, etc.
Leakproof zinc-carbon ...	N	1·5	Good	No risk of leakage of corrosive electrolyte	Photographic uses generally, bulb and electronic flash, small motors
Layer type zinc-carbon ...	N	1.5	Poor	Compact high-tension source	Capacitor flash guns; some types of electronic flash
High-energy alkaline ...	N	1·5	Good	High energy and current capacity	Continuous, heavy drain—e.g. for motor drives in movie cameras, tape recorders and record players.
Mercury	N	1·35	Excellent	High capacity and constant voltage	Portable transistorized equipment. Constant voltage applications. Cadmium sulphide photo cells
Nickel-iron	R	1·20	Excellent	Robust and foolproof	Heavy-duty power supplies, driving professional cine cameras
Nickel-cadmium	R	1·5	Excellent	Not affected by overcharging or being left discharged for long periods. Sealed-in electrolyte	Portable, high-consumption equipment electronic flash, tape recorders.
Silver-zinc	R	1.5	Good	Highest capacity for bulk of any secondary cell	All applications where bulk and weight must be kept to minimum
Silver-cadmium	R	1·5	Excellent	Similar to above with emphasis on long life and constant voltage	As above but where robustness, long life and constant voltage justify more weight and bulk
Lead-acid	R	2·0	Good	Low cost	Heavy duty where weight is not a disadvantage.

* N = Non-rechargeable; R = Rechargeable.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

has been used on heavy duty equipment for over half a century but in recent years small, hermetically-sealed versions have been developed and these have a wide application in photographic work.

The basic nickel-cadmium cell consists of nickel hydroxide (positive) and cadmium (negative) electrodes immersed in a potassium hydroxide electrolyte. Normally, when charging is complete, the cell liberates free hydrogen at the negative and free oxygen at the positive electrode.

However, by designing the cell in such a way that there is an excess of cadmium, the nickel hydroxide electrode reaches full charge first and liberates oxygen which at once reacts with the cadmium and does not exist as a free gas. No hydrogen forms on the cadmium, since it is still short of full charge, so there is no free gas to disperse. As a result the cell can be completely sealed and used in the most vulnerable equipment.

Miniature nickel-cadmium accumulators are sold in a packaged unit complete with their own charging system consisting of a mains transformer, a half-wave rectifier, voltage dropping resistance and a 2-pin mains plug. The whole unit is simply plugged into a mains outlet for charging whenever necessary. As a rule charging is completed in less than 24 hours, so that the equipment can be charged overnight ready for the next day.

This is the form in which the accumulator is contained in portable electronic flash units or tape recorders.

Nickel-cadmium accumulators will stand more abuse than any other type of storage battery, and—like the nickel-iron type—need no maintenance. The sealed types are being increasingly used in photographic equipment, particularly for small motorized systems—even of cameras.

Silver-Zinc Accumulators. Silver-zinc accumulators are approximately one-third the weight and volume of other types of storage battery of the same capacity. At low discharge rates they maintain a practically constant voltage and they can be discharged at a high rate without loss of capacity.

The silver (positive) and zinc (negative) plates are immersed in an alkaline (caustic soda) electrolyte and encased in a plastic case under lateral pressure which prevents shedding of the active material.

This type of storage battery is more expensive than lead-acid or nickel-iron alkaline batteries, but its small size and high output make it very suitable for powering portable photographic equipment and apparatus. Silver-zinc units completely sealed in resin are manufactured to drive automatic camera mechanisms in rocket-borne space equipment.

Silver-Cadmium Accumulators. This battery has many of the advantages of the silver-zinc type. Capacity-weight ratio, while not as good as for a silver-zinc battery, is still 2½ times greater than with other rechargeable batteries. Its two great virtues are its long life and its resistance to knocks and vibration. In these respects it is superior to the silver-zinc accumulator. F.P.

BAYARD, HIPPOLYTE, 1801–87. French amateur photographer and Civil Servant. Discovered an original silver iodide negative paper process early in 1839 and exhibited direct positive prints produced by another process in June, 1839 (i.e., before Daguerre's invention was published) at a charity bazaar in Paris. Founder member of the Société Heliographique, 1851, and was for 15 years (1866–81) the Honorary Secretary of the Société Française de Photographie (French Society of Photography). Biography by Lo Duca (Paris 1943).

BAYLEY, ROGER CHILD, 1869–1934. English writer of textbooks and guides to photography. Editor of *Photography* and later of *Focus* and *Amateur Photographer*.

BEAM SPLITTER. Arrangement of mirrors or prisms to divide a beam of light into two or more parts.

There are two principal forms: one which divides the beam transversely and deflects each half in different directions—for instance, a beam directed at the apex of a prism is divided at the apex and each part reflected in different directions by each of the oblique faces.

The other form is when the light energy within the whole beam is divided along two or more channels; for instance, a beam falling on the surface of a transparent medium is partially reflected and partially transmitted. The surface of the mirror or prism is usually semi-metalized to increase the proportion of the light reflected.

When reflected and transmitted beams are required to be of equal intensity, metallized glass beam splitters have the disadvantage of considerable light absorption. By using films (on glass) of bismuth oxide or zinc sulphide, working on an interference principle, almost zero absorption is achieved.

An example of the first type of beam splitter is that used to project stereoscopic films or slides in which the pairs of pictures are arranged side by side, the projector having a single optical system. The stereo attachment, as it is called, is fitted to the projector lens. The beam is divided by a 90° prism, the light from one picture going to the left and that from the other going to the right.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

These two beams are then reflected forward again by two further prisms set at the necessary angles to super-impose the two pictures on the screen.

A similar device is used on the camera to take the stereo pictures. Used in reverse in this way it is strictly no longer a beam splitter, although it is sometimes referred to as such.

The type based on semi-metallized reflectors used to be used in one-shot colour cameras. The requirement was to triplicate the image produced by a single lens so as to obtain three colour-separation negatives. Two semi-metallized mirrors of glass or collodion (pellicles) were arranged at suitable angles within the camera to intercept the light from the lens and direct part to one side and part to the other. At the same time they allowed part of the light to continue to the third focal plane. Thus three matched images were produced. A comparable system is still used in present day television cameras.

If two of the films or plates were used together as a bipack, only two images were required and therefore one reflector.

Certain automatic exposure control systems in enlargers and special cameras use beam splitters to direct some of the light to an exposure meter or photo-multiplier cell. The amount of light diverted in this way is usually around 5–10 per cent of the image forming light.

Prismatic beam splitters are normally used for small format cameras, such as professional 35 mm. cine equipment. They also find application in various optical instruments, such as binocular microscopes.

Amateur cine cameras frequently use beam splitters to provide a through-the-lens reflex finder. Here two prisms are cemented together with a semi-reflecting interface. This diverts a small proportion of the light from the optical path inside the lens to another optical system belonging to the finder. A further beam splitter may also be used to divert part of this light to an exposure meter cell for through-the-lens exposure measurement.

Beam splitters need not divide the light simultaneously along two channels, but can also do so alternately. An example is the reflex shutter of cine cameras which allows the light to pass through to the film during the open phase of the shutter, and reflects it into a viewfinder during the closed phase.

BEARD, RICHARD. Dates unknown. British daguerreotypist. Formerly a London coal merchant and patent speculator, he bought Daguerre's British patent for the daguerreotype process in 1841 and held a monopoly until 1853.

Introduced into Britain Wolcott's mirror camera and use of blue glass for glazing the studio. These, coupled with his employee J. F. Goddard's acceleration of the plate with bromine, enabled Beard to open the first photographic portrait studio in Britain—probably in Europe—at the Royal Polytechnic Institution, London, on 23 March 1841. In 1842 he patented colouring daguerreotypes, using stencils and powder colours. Beard quickly made a fortune from his four London studios and many licencees but lost it again in protracted lawsuits against infringers of the patent, and became bankrupt in 1850.

BECK EFFECT. Increase in the light intensity and other characteristics of a D.C. carbon arc when the positive carbon is loaded with certain metallic salts and the arc is worked at a high current density. This is the basic principle of the high intensity arc.

BECQUEREL, EDMOND, 1820–91. French physicist. Investigated the photographic process and demonstrated in 1840 that an underexposed daguerreotype plate could be intensified by diffused supplementary exposure under red glass (the Becquerel effect). Observed the direct coloration of light-sensitive silver chloride about 1847. Discovered the photogalvanic effect, 1839.

BECQUEREL EFFECT. Intensification of a latent image by exposure to light to which the emulsion is otherwise insensitive. An image on print out paper can be intensified if it is exposed to green light before fixing, and if a latent X-ray image is exposed to white light a silver image eventually builds up on the areas that have already received an exposure. Apart from this, silver bromide emulsions do not exhibit the effect.

BEDFORD, FRANCIS, 1816–94. English landscape and architectural photographer (originally a lithographer); became well-known in the mid-nineteenth century. Was commanded by Queen Victoria to accompany the Prince of Wales (Edward VII) on his educational tour of the Middle East in 1862. One hundred and seventy-two of Bedford's several hundred photographs were published the following year.

BEEF-CAKE. (Slang.) Photograph of a man posed to display his physique; masculine equivalent of "cheese-cake". The subjects are usually professional or amateur "strong men", pugilists and the like.

BEESWAX. Hard yellow wax, soluble in hot turpentine, obtained from the honeycomb of the honey bee. It is the basis of dopes for giving depth and lustre to exhibition prints; it is sometimes made into a polish for glass surfaces used in glazing prints and it may be used on the temporary support surface in the double transfer carbon process.

BELGIUM

Belgium has played an important part in the development of photography and cinematography.

History. In a thesis written for his doctor's degree in 1829 the physicist, J. A. F. Plateau (1801–83), formulated the laws of the persistence of vision on which cinematography is based. He calculated that the duration of a visual impression from the moment of maximum intensity to the moment when it is only just perceptible is about one-third second.

Basing his design on Faraday's description of the stroboscopic illusion as published in the Journal of the Royal Institution of Great Britain in 1831, Plateau constructed the phenakistoscope, the first known cinematograph apparatus. The instrument, which appeared in 1833, consisted of a cardboard disc with a number of holes punched near the circumference and a series of figures painted on one side. The disc was spun round on its axis with the drawings facing a mirror and when the operator observed the images in the mirror through the holes, an illusion of movement was produced.

The first production model of Plateau's phenakistocope was sold in Paris and London. Meanwhile an improved instrument made by Stampfer of Vienna as well as the Zoetrope of English manufacture had appeared. In collaboration with C. W. Ackermann, Plateau soon produced an improved apparatus under the name of fantascope. This achieved great success, but though it already embodied the essential principles of cinematography, another sixty years were to pass before the first film appeared on the screen.

The modern reflex method of document copying was invented by the German, Albrecht Breyer (1812–70), when studying at Liége University. It was described in a letter to the Brussels Academy of Sciences, dated 14th August, 1839, five days before the meeting of the Paris Academy at which D. J. F. Arago gave the full description of Daguerre's process. Albrecht Breyer used a silver chloride paper of his own manufacture which he called "heliographic" and succeeded in making direct copies of line documents, without the need for optical apparatus, within seven minutes. As his letter to the Brussels Academy indicates, he was fully aware of the theoretical principles of his process, which have remained basically unchanged to this day, but did not himself exploit the process further. It was revived by P. Yvon in 1891 and J. H. Player in 1896, and is often now referred to as Player-type in consequence.

The first Belgian manufacturer of sensitized materials on a large scale was D. C. E. van Monckhoven (1834–82). In 1852 van Monckhoven published a manual of photography which was translated into four languages. In 1879 he discovered that the ripening of silver bromide is notably accelerated by the addition of ammonia. This discovery had a decisive influence on the manufacture of sensitive materials, in particular, the dry plate.

In his laboratory at Ghent, van Monckhoven prepared emulsions for sale both direct to photographers and to other manufacturers who coated them on to glass plates. One such manufacturer produced 1,300 plates per day. In a prospectus van Monckhoven stated that his dry gelatin-bromide emulsion contained exactly half its weight of silver bromide and was ideal for photographers wishing to prepare large-size glass plates. The Ghent plant also produced carbon paper in various types for single and double transfer.

After van Monckhoven's death the manufacture of sensitized materials was carried on by smaller firms, one of which was owned by L. A. H. Baekeland (1863–1944). Baekeland settled in the U.S.A. in 1889, where he formed a company which manufactured the first silver chloride developing paper. The company was later taken over by Eastman Kodak and Baekeland devoted himself to electro-chemistry and research into plastics. In 1909 he invented a synthetic substance which was called "bakelite" after him and has made his name famous. Baekeland became a professor at Columbia University and held a number of honorary degrees from other seats of learning.

Amongst other photographic research workers in Belgium the physicist André Callier is noteworthy for his discovery in 1909 of the absorption and scatter of light by the silver image grains in a photographic negative. The result of this selective scattering of the transmitted light is to increase the contrast of the projected image and emphasize scratches, etc., in enlargements.

At the time of Baekeland's departure for the U.S.A. Lieven Gevaert (1868–1935) opened a small laboratory for the manufacture of photographic paper. A company bearing the name Société L. Gevaert & Cie. was formed in 1894; within a few years it had grown considerably.

Science. There are adequate facilities for study of the theory of the photographic process at the universities of Ghent, Liége and Louvain. Typical subjects of study are: the nature of the centres of sensitivity formed on silver halide crystals during the preparation of the emulsion; action of light on light-sensitive crystals and the formation of the latent image; the nature of the latent image and the changes it undergoes under the influence of light and the action of the developer. For many years extensive research has been devoted to evolve scientifically founded methods for measuring emulsion characteristics. Remarkable results have been achieved, e.g., in connection with resolving power.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

At Louvain University important research is proceeding with a view to finding macromolecular products to serve as protective colloids in the preparation of emulsions, to replace gelatin and as a support in place of the cellulose derivatives used at present.

Important research is also being carried out in the laboratories of Belgian factories.

Organizations and Periodicals. The principal organizations in Belgium are la Fédération des Unions Professionnelles Photographiques de Belgique (Federation of Professional Photographic Unions of Belgium), which is the body of professional photographers and photographic dealers, and the Chambre Syndicale des Négociants en Articles Photographiques (Photographic Retailers Association).

Photographic periodicals published in Belgium are called *Photo-tribune*, *Video* and *Spotlight*.

Amateur Photography. At the turn of the century the most notable successes at international photographic exhibitions were obtained by the Belgian pictorialists Alexandre, F. Leys, G. Marisiaux, Léonard Misonne, L. Sneyers, Vanderkindere and Willems, all of them except the first-named being amateurs. Misonne's masterly landscapes are still an inspiration to the young workers of today. In the portrayal of the everyday utensils of modern life and the use of close-ups the Frenchman Dubreuil, who lived in Belgium at the beginning of the century, anticipated the modern approach to photography.

There is now a large and well organized amateur photographic movement in Belgium. Clubs are active in all towns and large centres of population, the majority being affiliated to the F.B.C.P. (Belgian Federation of Photographic Clubs). The Federation was founded in 1947 and at the end of 1964 comprised 160 clubs with a total membership of about 7,500. It arranges national and international competitions.

There is also a strong movement of amateur cinematographers, Facineb, uniting 60 clubs, total membership about 1,500. H.C.

Industry. The manufacture of photographic goods in Belgium is confined almost entirely to sensitized materials and chemicals, the industry being dominated by the major company Gevaert-Agfa N.V., established at Antwerp. This organization undertakes the production of all types of photographic materials, in particular X-ray film and sensitized paper, and has shown steady growth in size and the value of output over the past five years. The Company currently employs 9,300 workpeople nationally, and merged with Agfa in July 1964.

As a result of the industry's structure, no production statistics are published. It is possible, however, to estimate the annual value of output by relating the total exports of sensitized goods each year to information contained in the Gevaert published Report, and the figures resulting from this are shown in the table.

Imports. The value of imported photographic equipment and materials has shown considerable expansion since 1959, reaching a total of Fr. 655·9 million in 1963.

As might be expected, a large part of this is due to apparatus, among which still cameras hold the leading position. In 1963, imports of these attained 239,000 units with a value of Fr. 99·2 million, the principal sources of supply being West Germany (74,600 cameras worth Fr. 53·4 million) and Japan (19,800 cameras worth Fr. 17·1 million).

Cine camera imports have followed a rising trend during the past five years to reach 14,100 units valued at Fr. 41·7 million in 1963, the majority of which are 8 mm. models. Japan is the leading supplier of this gauge, with 5,300 cameras worth Fr. 9·3 million, whilst West Germany supplied 4,500 units with a value of Fr. 13·5 million in the year. Imports of cine projectors have also risen during the period totalling 11,000 units valued at Fr. 31·4 million in 1963, among which 8 mm. gauge types also predominated. The bulk of the latter came from Austria (4,800 projectors worth 9·8 million), whilst West Germany supplied 1,200 units worth Fr. 3·4 million.

Still projectors were supplied chiefly by West Germany in 1963, whose share amounted to 12,800 units with a value of Fr. 18·2 million out of the total of 19,200 projectors worth Fr. 30·4 million.

Imports of sensitized materials and chemicals have nearly doubled in value in the period 1959 to 1963, reaching a total of Fr. 281·6 million in the latter year. Within the overall figure, sensitized paper is the most important product with a value of Fr. 118·8 million, the principal sources of which are (in Fr. million), France (49·4), West Germany (14·4), and the U.S.A. (8·4).

Among other leading items in the field is still film, the 1963 total value of which being composed of roll film worth Fr. 27·6 million and miniature format film worth Fr. 16·7 million. The main suppliers of roll film during the year were West Germany (Fr. 9·9 million) and the U.S.A. (Fr. 9·7 million), whilst the U.S.A. also provided Fr. 12·9 million's worth of the miniature type.

Cine film imports have continued to follow a rising trend over the past five years to a total of 6·1 million metres worth Fr. 33·1 million in 1963. Of this, 16 mm. and smaller gauge stock accounted for 5·3 million metres valued at Fr. 26·7 million, the principal source being the U.S.A. with 2·7 million metres worth Fr. 18·2 million.

Exports. The value of exported photographic goods has recorded a steady increase in the past five years to a total of Fr. 3,505 million in 1963. By far the greater part of this is composed of sensitized materials, and the relatively small amount of equipment consists almost entirely

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

of re-exported items manufactured in other countries.

All sensitized products have shared in the general growth during the period, the two principal materials being photographic paper and X-ray film and plates. Exports of the former reached Fr. 888·7 million in 1963, of which the U.S.A. received Fr. 227·2 million, West Germany Fr. 142·5 million, and the United Kingdom Fr. 119·6 million. The total of Fr. 1067·2 million for X-ray film and plates during the year was composed mainly of sheet film (Fr. 958·6 million), whilst the main markets for the group as a whole were again the U.S.A. (Fr. 263·1 million) and West Germany (Fr. 163·4 million).

Cine film exports constitute a substantial part of the total, being composed in 1963 of 194·2 million metres worth Fr. 443·9 million of 35 mm. stock and 107·5 million metres worth Fr. 208·3 million of 16 mm. and smaller gauge film. Major purchasers of both types during the year were the U.S.A. (96·0 million metres valued at Fr. 145·7 million) and West Germany (29·0 million metres with a value of 72·7 million).

Exports of still film in 1963 consisted of roll film worth Fr. 173·1 million (Fr. 135·1 million being black-and-white stock), together with miniature format type valued at Fr. 64·8 million (of which Fr. 47·3 million was colour film). Leading markets for these products are the United States and West Germany, receiving totals of Fr. 76·6 million and Fr. 25·7 million respectively.

BELITSKI'S REDUCER. Chemical reducer for negatives, consisting of a solution of ferric potassium citrate or oxalate in an acid-fixing bath.

See also: *Reducing.*

BELLOWS. Collapsible and light-tight sleeve joining the lens to the back of the camera in all but a number of small hand cameras, box cameras, and miniature cameras. Nicéphore Niépce had a square bellows camera constructed, probably by Charles Chevalier, sometime between 1826 and Niépce's death in 1833. (This camera is preserved at the Musée Denon, Châlon-sur-Sâone.) Camera bellows were at one time made of either leather or rubberized fabric. Nowadays bellows of plastic or plasticized fabric are being increasingly used.

It is not difficult to make bellows either in these materials or in stout opaque paper to meet temporary requirements. For parallel bellows, cut a rectangle of the material with the width equal to one and one-third times the maximum bellows extension required plus an allowance for attachment. The length should be the average of the distances round the outside and inside of the bellows when compressed, plus an allowance for the overlap in joining the two ends together. The material is then folded and joined up to complete the bellows.

The method of repairing bellows is dictated

MAKING BELLOWS. Top: Mark out a piece of the material in the required size allowing sufficient for overlap in glueing together. Score the folds as shown. Bottom: Bend up the tube and glue together. Then fold along the scored lines: in one direction on the solid lines, and in the opposite direction along the dotted ones. A knife will help in completing each fold. Crease the folds to make them permanent. Finally stick the ends of the bellows to suitable panels.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

by the particular nature of the damage. The usual faults that develop are pinholes at the corners of the folds. If they are extensive, as they may be if the material is perishing, repairs are not likely to be satisfactory. But small holes due to abrasions or accident can be repaired by applying a patch of black paper or other thin opaque material. Another effective method is to seal the hole with rubber solution or cellulose cement into which a little lamp black has been worked.

See also: *Home-made equipment; Repairs to cameras.*

BELLOWS EXTENSION. Adjustable extension unit, consisting of bellows connecting a movable front panel with a fixed rear section, intended for fitting on cameras with interchangeable lenses. The rear plate attaches to the front of the camera body, while the lens goes into the front panel. Such a unit provides a wide range of focusing distances, especially for close-ups and macro-photography.

See also: *Extension bellows.*

BENNETT, CHARLES, 18??–1927. English amateur photographer. In 1878 published his method of increasing the photographic sensitivity of gelatine emulsions by prolonged heating at a temperature of about 90° F.

BENZENE. Used as a solvent for waxes and resins, e.g., of the bitumen in certain photomechanical reproduction processes.

Formula and molecular weight: C_6H_6; 78.

Characteristics: A colourless liquid smelling like coal gas.

Solubility: mixes in all proportions with alcohol and ether; insoluble in water.

See also: *Benzine.*

BENZINE. (Benzoline). Used as a solvent for fats and gums, a lamp oil, and as a dry cleaning fluid.

Formula and molecular weight: Variable.

Characteristics: A colourless, volatile liquid obtained by the fractional distillation of petroleum. Not to be confused with benzene which is a coal-tar derivative.

Solubility: Similar to benzene.

BENZTRIAZOLE· Anti-fogging agent.

Formula and molecular weight: $C_6H_5N_3$; 119.

Characteristics: White needle crystals.

Solubility: Slightly soluble in water.

See also: *Developer improver.*

BERTALL (Vicomte d'Arnoux), 1820–82. French caricaturist and book illustrator, also active as a portrait photographer of celebrities in the 1860s and 1870s.

BERTHON, RODOLPHE. Dates unknown. French engineer and astronomical optician. Developed the lenticular screen additive process which was originally patented by Keller-Dorian in 1908, since made commercially available as Kodacolor (1928) and Agfacolor (1931) for amateur cinematography, also used (1936) in commercial cinemas.

BERTILLON, ALPHONSE, 1854–1914. French anthropologist. Introduced the identification of criminals by anthropometry which he described in his *Photographie Judiciaire* (1890).

BERTSCH, ADOLPHE, Dates unknown. French microscopist and photographer. Introduced, in July 1860, the chambre noire automatique, a 4 ins. square metal box with frame viewfinder, spirit level, and fixed focus (automatic) lens of 3 ins. focal length. The 2¼ ins. square negatives could be enlarged 10 × diameter with Bertsch's megascope or solar enlarger. This was a forerunner of the modern system of a small camera producing negatives for enlargement at a period when enlarging was seldom practised.

BETWEEN-LENS SHUTTER. Shutter that operates between the back and front lens components. This type of shutter includes some of the finest made and is the most popular type for hand cameras with non-interchangeable lenses. Sometimes this term is applied to all shutters of the same basic construction although they may in fact be placed behind the lens.

BICHROMATED ALBUMEN PROCESS. Normal photomechanical reproduction process for making line blocks. A metal plate is coated with albumen sensitized with ammonium bichromate. When it is exposed behind the negative the coating is rendered insoluble wherever the light acts. Washing the plate leaves behind an image in undissolved albumen. The line block is made by treating this image with powdered bitumen and etching away the unprotected metal. This process is rapidly becoming obsolete.

BICHROMATE POISONING. Painful rash or outbreak of small ulcers on the hands sometimes suffered by workers who handle potassium bichromate.

See also: *Skin affections.*

BICHROMATE PROCESSES. Bichromate is the usual trade term for chromium salts of potassium, ammonium, or sodium of the Cr_2O_7 group, which are more popularly called dichromates. Their light hardening effect in association with organic colloids such as gum, glue, albu-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

men and gelatin is exploited in a number of photographic and photomechanical processes. Among the many such bichromate processes are most of the control processes and a number of photomechanical reproduction processes.

See also: *Control processes; Dusting-on process; Glass pctures; Pigment processes.*

BI-CONCAVE. Term applied to a lens indicating that each of its faces curves inwards towards the centre.

BI-CONVEX. Term indicating that each of the outer faces of a lens curves outwards away from the centre.

BIG GAME. The authorities in the world's big-game areas are becoming more interested in preserving wild animal life than in allowing it to be indiscriminately killed by the hunter. This is having a two-fold effect: travellers are being forced to do their shooting with the camera instead of the rifle, and the animals are becoming tamer. In many of the big game preserves of Africa and North America, it is possible to photograph more wild animals in the course of a day's motor ride than a hunter could hope to see in a month.

The Subject. As in every other branch of photography the man who knows the most about his subject gets the best pictures. Wild animals vary in their habits and the technique that works best with one species is useless with another.

Elephants have very keen scent but relatively poor vision and hearing. So long as there is a breeze, however slight, the photographer can work upwind to within fairly close range. Even so, there is more hope of getting a picture with a telephoto than with a normal angle lens.

Lions, surprisingly, are probably the easiest of all the larger animals to photograph. They pay very little attention to the photographer as long as he is in a car and keeps more than about four yards away. In addition to having light-coloured skins, lions frequent open scrub country where the light is in any case good for photography.

Photographers who specialize in big game photography agree that the danger involved in photographing lions is overrated. Lions are actually known to warn off photographers who approach too close. They do this by making a rush at the photographer, but once he retreats make no attempt to take the matter further.

Rhinoceros are both short-sighted and short-tempered. The rhino has very keen hearing and if he is being watched from a hide is apt to shy away at the slightest unusual sound. In common with most other animals in game reserves, the rhinoceros has become accustomed to seeing motor cars and generally takes little notice of them. For this reason it is easier to photograph this animal from a motor car than from a hide, and safer than on foot.

Buffalo are the most dangerous and difficult of all African wild animals to photograph. They are nocturnal in their habits, and tend to stay in the thick bush. The African buffalo is a formidable creature and one of the very few animals that will attack a man on sight. There are places, however, like the Belgian Congo National Park and the Queen Elizabeth National Park in Uganda where buffalo can be approached near enough to give good results with a telephoto lens. These particular beasts are relatively tame because they have been allowed to go unmolested for some generations. Another way to photograph buffalo is to arrange an automatic shutter release device at a water hole that the animal is known to use.

Zebra, antelopes and other swift-footed creatures can be photographed early or late in the day from a hide set up near their water hole. In game parks and reserves where they are unharassed by man, they can be approached by car or lorry close enough to be photographed through a telephoto lens. A number of striking action shots have, however, been taken of them from low-flying aircraft but the practice is frowned on by the game wardens.

Giraffes belong to the relatively tame species that can be photographed from a car and are quite safe to approach on foot. Once they become aware of the presence of the photographer, however, their long legs rapidly carry them out of range of even a telephoto lens.

Hippopotamuses, again, are animals not so much dangerous as shy, and they must be stalked cautiously from the down-wind side. The hippo is usually found in herds and it spends most of the day in the water, coming out mostly at night and only rarely in the daytime. So the most characteristic photographs are those which show the animal partly submerged in its natural element. The hippopotamus has capacious lungs; once scared it dives and can remain submerged long enough to exhaust the patience of the most ardent photographer.

Technique. There are three ways of going after big game with a camera: on foot, by car and from a hide. In practice, stalking the game on foot is the least effective method and where the terrain is suitable, photographing from a car is the easiest and safest way of getting pictures. A hide has its own advantages, but it ties the photographer down to one place with no choice of viewpoint and lighting.

Photographing from a Car. When working from a car, the photographer generally stands on the front seat and shoots from the open sunshine roof. In this way he can get the driver to take him around the animal to find the best viewpoint and lighting. It is a fact that most animals are less disturbed by a car than by a man on foot. Fortunately, too, the surface of the ground in many game reserves is reasonably level and there is no need for the car to stick to the road.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Most drivers quite naturally prefer to keep the engine of the car running when close to potentially dangerous animals. For this reason it is never wise to rest the camera on the edge of the sunshine roof or vibration is almost certain to spoil the picture.

Photographing from a Hide. Hides are always constructed well above the ground in the neighbourhood of a water hole or salt lick known to be frequented by the game. Some hides are luxurious affairs equipped with beds and other amenities intended to make the hours of waiting as comfortable as possible. The photographer must be prepared to enter the hide many hours before the game shows itself—that is, during the early morning and late evening—and generally he will have to stay there until the following day.

The photographer who works from a hide can always find plenty of places to steady his camera during the exposure and can, if the light is poor, use a tripod and give quite long time exposures. It is always better if the subject can be photographed with a telephoto lens some distance away from the hide. This helps to offset the high viewpoint; if animals are photographed at close range with an ordinary lens the camera looks down and gives an uninteresting plan view.

The most serious disadvantage of a hide is that it imposes a fixed viewpoint and direction of lighting. Once in the hide the photographer has no way of shifting his viewpoint.

Lighting. The light in the real bush or jungle is always too weak for instantaneous exposures even at midday. Fortunately, however, most big game roams in the more open scrub country where the light is good. The hours around midday are practically useless for photography because then the sun is more or less vertically overhead, giving hard uninteresting lighting. Early morning and late afternoon in the dry and sunny season are the best times.

Sensitized Material. The colouring of most animals and their surroundings is of a sort that comes out well on fast panchromatic film. This usually gives excellent rendering of the tones of dark green foliage, red earth and reddish-brown skin and hide. As the sky seldom if ever comes into the picture, there is rarely any need for a filter, all the tones of the subject being at one end of the spectrum.

Exposure. As a tripod is generally out of the question and the camera must be held, exposures are never longer than 1/100th second. Even at this speed it is not easy to avoid camera shake when using a telephoto lens. However, using fast panchromatic film in the average morning and late afternoon light it is generally possible to use this shutter speed or even 1/300th second with a lens aperture of *f* 8. This aperture is usually just small enough to give the necessary depth of field for the average big game photograph. Animals in motion can be taken at much higher shutter speeds and bigger lens apertures provided that they are far enough away from the camera.

Equipment. The lens is the most important item of equipment in big game photography. Because it is rarely possible or advisable to go closer than about 40 yards from the subject, a good telephoto lens of 3× to 4× magnifying power is absolutely essential. This in its turn dictates the use of either a reflex camera or a miniature with coupled focusing.

In practice both of these types of camera are used. Those who favour the miniature often have it mounted on a gun stock with triggers for firing the shutter and winding on the film. The camera is then aimed as though it were a rifle; this method of mounting helps to overcome the added risk of camera shake with the long focus lens.

The single lens reflex, taking, say, a 2¼ ins. square film, has the advantage of taking a bigger negative that requires less enlargement and consequently gives crisper rendering of hair and other essential fine detail. G. de H.

See also: *Animals; Zoo.*
Book: *Camera on Safari*, by John Sherman (London).

BINOCULAR VISION. Visual perception of objects with two eyes.

The fundamental difference between seeing with one and with two eyes is in the appreciation of the depth of the subject. When an object is looked at through two eyes, each eye sees a little more than the other of its own side of the object. In addition each eye sees the object against a different part of the background. The first difference increases as the object comes closer to the eye, the second increases as it gets farther away from the background. When the separate pictures seen by the two eyes are fused into a single impression in the brain, these effects combine to give an impression of the depth of the subject and its position in space between the observer and the background—i.e., a stereoscopic picture.

The stereoscopic effect of binocular vision grows less as the subjects get farther away—i.e., as the separation of the eyes becomes less and less in proportion to the distance of the subjects. After a certain point is reached, both eyes see substantially the same picture and the sensation of depth is no longer apparent. For a scene viewed at a given distance, the stereoscopic effect is greater the more the scene extends in depth.

BIOLOGY. The study of the various phenomena of living plant and animal matter, most of which are capable of being recorded by photographic methods, is known as biology. The subjects studied may range from microscopic spores to complete botanical and zoological specimens. So biological photo-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

graphy makes use of normal, macro- and micro-photographic techniques. Some work is also done nowadays with cinematography, and both still and moving pictures may be in black-and-white or colour.

Biological photography is simply an application of the equipment and techniques of botanical, medical and zoological photography. It may be carried out in the field or the laboratory; some projects can be covered by a single worker with simple portable equipment, others call for a staff of scientists and assistants with highly specialized and costly equipment.

Elementary Organisms. The biologist's interest starts with the study of living cells. In this branch, while specimens may be collected in the field, all the photographic work takes place in the studio and is generally a matter of straightforward photomicrography. The most serious problem of photographing living micro-organisms used to be the difficulty of finding a light bright enough to enable instantaneous exposures to be given without at the same time drying out or killing the specimen. The advent of electronic flash, however, has made both still and cine high speed photomicrography of living specimens very much easier. As the light is practically cold, there is no danger to the specimen. Still exposures can be made by simply operating the flash while the normal room illumination is switched off, the duration of the flash being short enough to arrest the movement of the liveliest specimen. Cine photography can be carried out by using a stroboscopic flash synchronized with the camera shutter.

Primitive Life. In the study of primitive forms of life it is necessary to photograph fossil remains, both in the field and the laboratory. Field pictures are necessary to show the relation of the fossil to the material in which it is embedded. The laboratory pictures show the fossil from several angles against a plain background and include a graduated rule to show the actual size. Such photographs alongside those of the present day forms of related organisms show how the subject has changed in the course of centuries of evolution.

Growth. The biologist uses photography to record the development of the embryo. This involves a series of pictures of a number of similar embryonic specimens, taken at intervals to give the effect of a single embryo photographed at different stages of development. The successive specimens must therefore be taken from the same angle and under identical lighting conditions. Such a photographic series may also be supplemented by a series of X-ray photographs of a single developing specimen. The X-ray exposures must be made from the same angle as the photographs so that the two can be compared. The subsequent growth of the organism or creature is recorded by photographing it at regular intervals alongside a scale or preferably against a background ruled off in squares. Photographs made in this way are invaluable for studying the effect on animal growth of different methods of feeding. This branch of biology may call successively for micro, macro, normal photographic and X-ray equipment.

Structure. The internal and external form of the subject is one of its most important characteristics and one that lends itself to photographic methods of recording. Here the camera is first called upon to make accurate records of the outward appearance, showing coloration, texture and modelling. Further records are then made at various stages of dissection to show, for instance, the muscular and nervous systems, the bodily organs, and the skeletal structure. All this work is carried out in the laboratory; it has no relation to the subject in its natural surroundings.

Form. Morphology, or the study of organic form and how it develops, is an important branch of biology. Here also photographic records are used extensively. Typical specimens are photographed under controlled conditions —if possible in the laboratory—to reveal characteristic features of the species or class.

Most forms of life, while conforming to definite characteristics, exhibit certain typical variations—e.g., dwarfs, giants and "sports". These deviations from the standard form can be studied by comparative photographs showing the normal and the variant. Such photographs must be taken under comparable conditions, and the biologist must be certain that his standard is in fact typical of the species.

Heredity. Biologists are also interested in the way in which characteristics are handed on from one generation to the next, and in this field the camera is employed to record the characteristics of successive generations of a wide variety of plants, insects, fish and animals. The points of interest may range from the cell structure to the whole organism and involve extensive series of pictures made in both field and laboratory.

Behaviour. The behaviour of the subject under normal and abnormal conditions provides an unlimited choice of material for photography. Studies of this type include the courtship, mating and breeding activities of insects, birds, fish and animals, life cycles of parasites, response to seasonal climatic and temperature changes and the like. Although much of the bread-and-butter work in this field is carried out with still cameras of all types, an increasing amount is being done with cine cameras, and the results often have an educational and even an entertainment value far beyond the immediate intention of the makers of the film. Their early success, in fact, has inspired the production of a type of nature film in which, by careful production, cutting, and "dubbing" of sound, factual studies of insect and animal behaviour turn a biological study into a popular cinema feature.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Ethnology. Ethnographic surveys—i.e. the recording of race varieties and evolutionary changes—form an important part of the science of biology. The scope of such surveys extends to the various race types scattered over the earth's surface and backwards in time to the earliest traces of human life.

Much has been done in attempting to establish racial characteristics by making "average" portraits, consisting of dozens of superimposed photographs of separate individuals. The biologist, however, is more interested in producing sharp pictures of typical individuals which show clearly the details of skin and hair character, bone formation, stature and proportions peculiar to the race as a whole.

Equipment. The equipment for biological photography is simply the most suitable selection of normal photographic equipment for the particular project being followed; there is no special biological camera, since the work may call for anything from a microscope camera to a large plate or reflex camera. Where the funds available will not cover the cost of special cameras and equipment for each branch of the work, a 35 mm. miniature system—including camera, short, normal and long focus lenses, close-up focusing device, portable electronic flash unit, microscope attachment and possibly a reflex attachment—is the best compromise. The availability of attachments may depend on the camera make. F.P.

BIOT, JEAN BAPTISTE, 1774–1864. French astronomer, chemist, mathematician, and member of the French Academy. He was one of the scientists appointed to report on Daguerre's discovery. Biot had known of Daguerre's work and so was able to support M. Arago and Alexander von Humbold in the report made to the Academy on 7th January 1839. This caused a sensation and in July 1839, a bill was passed which gave to Daguerre a pension of 6,000 francs, and to Isidore Niépce a pension of 4,000 francs on condition that Daguerre described his process in full.

BIOW, HERMANN, 1810–50. German daguerreotypist. Opened a studio at Altona near Hamburg 15th September 1841. With C. F. Stelzner, his partner for seven months, took earliest news photographs of great fire at Hamburg, May 1842. 1846–50, took portraits of many royalties and celebrities in Dresden, Berlin and Frankfurt, for his projected National Gallery of Photographic Portraits, 126 of which were published as lithographs in 1849.

BI-PACK. Combination of two films placed emulsion to emulsion and exposed as one.

The two films are differently sensitized to yield colour separation negatives. The two negatives can be used for two-colour photography.

Alternatively the bi-pack can be used in one focal plane of a special single-reflector one-shot colour camera, with a single film in the other focal plane to give the third separation negative. This arrangement used to be employed extensively in colour cinematography.

BIRDS

The photography of birds is concerned with three main types of picture, each of which calls for its own technique and equipment. There are the pictures of nests with eggs in them; then there are the pictures of parent birds at the nest, either sitting on the eggs or feeding the young; and finally there is the most difficult branch of all—pictures of birds in the open country, on the tidal flats by the seashore or actually in flight.

NEST PHOTOGRAPHS

Photographs of just the nest are much easier to take than those which include birds or are of birds in the open.

Equipment. Nowadays, for photographs of nests and eggs, experienced bird photographers tend to use a hand-held miniature camera—preferably equipped with a long focus lens—in conjunction with a flash mounted on the camera (where the nest is in shadow).

This arrangement makes it possible to take excellent pictures of nests even when they are tucked away in a hedge or a hole. The powerful illumination of the flash allows the lens to be stopped right down to give sharp definition over the whole subject and at the same time to work at a shutter speed fast enough to avoid camera shake.

With this type of equipment it is possible to approach the nest without a lot of fuss and noise, take the photograph through any suitable break in the foliage, and then get away quickly and quietly. The whole operation is unlikely to worry even the shyest bird; some birds in fact will sit tight and if the eggs are the important thing, it may even be necessary to scare the bird off them.

Where possible, eggs in a nest should be photographed in colour, and with fast miniature lenses and high speed film this is no difficulty. However, it is important to get the colours exact; it isn't enough to produce a pleasing picture. Often the only way to tell the eggs of one species from another is by slight differences

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

SWING BACK AND TILTING BASE. Left and Centre: *A swing back on the camera will extend the effective depth of field available.* Right: *A tilting base allows easy yet rigid adjustment of camera angle. Useful with heavy cameras.*

in the tint of the shell or the colour of the markings on it. So the recommendations of the manufacturer of the film about exposure and filter technique should be followed to the letter, especially when using bulb or electronic flash (below).

It is as well to remember that, for the record, the colour and nature of the nest materials—grass, moss, leaves, mud—and the lining—wool, fur, feathers—are as important as the details of the eggs themselves. So the lighting should be directed—by a white card reflector if necessary—into the nest to light up the interior.

Again, the viewpoint must not be so close that the nest fills the whole frame. To provide a complete record the picture should include enough of the surroundings to illustrate the general character of the nesting site favoured by that particular bird—rocky ledge, grassy hollow, undergrowth or open branches.

Made in this way, pictures of nests with eggs take the place of the old fashioned birds egg collections. They convey more information and do no harm to the birds or their young, and they are so much more convienent to store, catalogue and exhibit.

In the past, the standard equipment for photographing nests and eggs was a plate camera mounted on a tripod. By comparison with modern miniature camera practice, this method has a number of disadvantages. When focusing close, the depth of field of the lens required to cover a 5 × 4 or half-plate is extremely limited. The only way to get a sharp image is to use the smallest possible stop in conjunction with the swing back. In addition, with lens panel focusing, every movement of the lens in or out alters the scale of magnification and calls for a corresponding movement of the camera support. So a focusing back is essential. Finally, the long exposures necessary with this set-up demand a tripod—a piece of equipment that can make photography in awkward places a difficult and frustrating business. However, many excellent nest photographs are still being produced by patient specialists who put up with all the disadvantages for the sake of the slightly better quality that comes from working with a bigger format.

Lighting. Subdued daylight is quite the best type of lighting as it shows up the markings on the eggs and the modelling of the shell to the best advantage. On bright days the direct rays of the sun must be prevented from shining on the subject and the photograph made by the diffused light from the sky.

However, flash illumination has the twin advantages of being independent of weather conditions and dispensing with the tripod. Bulb or electronic flash are equally suitable so long as the film maker's instructions about exposure and filter are followed. With this form of lighting it is important to ensure a clear field for the flash beam as well as the camera lens.

BIRDS AT THEIR NESTS

Birds are easiest to photograph when they are busy at their nests, either sitting on their eggs or feeding their young. Once the nest has been located, the photographer can be sure of being able to find the birds when and where he wants them. This is quite the easiest type of bird photography; once the nest has been located, the rest is just a matter of patience and straightforward photography. However, it is almost always necessary to work from cover, the form it takes depending on how far the camera is away from the subject. With a miniature camera equipped with a telephoto lens it is possible to work far enough away not to worry the bird, but close enough for a good picture. With a lens that dictates a closer position, the photographer and camera must be concealed completely in a specially constructed hide.

The Hide. The hide can always be improvised from branches or other suitable material gathered on the spot, but the serious bird photographer almost always uses a portable erection made up of light wooden struts and covered with cloth or fabric, so designed that it can be put together or dismantled in a few minutes. The hide is always big enough for the photographer to be able to work in comfort in view of the fact that he may have to spend hours waiting for his opportunity. Every sign of movement must be avoided, so if the sides

INSIDE THE HIDE. Have method in the hide, know where all equipment is placed so as to get at it instantly.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

and front of the hide are made of cloth they must be fixed firmly to prevent them from flapping in the wind.

The hide should be made as comfortable as possible because it may be in use for long periods of waiting. The camera should be set up and roughly focused before erecting the hide, otherwise it will be very difficult to erect the tripod and arrange the camera in the small space available.

Technique. The lens should point through a small hole in the front of the hide, and there should be a small peep-hole in a convenient place or a periscope in the top of the hide to give the photographer a clear view of the surroundings of the site focused.

The subject is generally very nervous on its first approach to the nest, and it is wise to allow the bird to feed its young three or four times before starting to make exposures. If the parent hears the slight click made by the shutter on its first visit, it may be scared off for a long time. But when once it discovers that there is no danger from the strange erection that has appeared close to its nest, it will take very little notice of unusual noises.

Equipment. The best camera for shooting from available cover is a miniature equipped with a telephoto lens—200 mm. to 400 mm. on a 35 mm. film is ideal. With such a long focal length a firm tripod is essential to avoid camera shake. Rangefinder focusing is preferable since it allows the lens to be focused at its working aperture, whereas an eye level reflex may have to be stopped down after focusing and the bird may move away in the meantime.

For working from a hide, a tripod-held miniature eye level reflex camera with a long focus lens—135 mm. on a 35 mm. film—is the best arrangement since it requires only one hole in the front of the hide.

The conventional large-format reflex camera is also suitable since its extra bulk is unimportant. With a reflex camera taking quarter-plates or 6 × 6 cm. films, a lens of about 9 ins. focal length serves for most subjects. A telephoto lens of 14 or 17 ins. focal length is better for photographs of waterfowl like ducks, geese and grebes on the open water, and waders feeding on the shore at low tide. As nests are usually built in shady places the lens should have a maximum aperture of at least *f* 4·5.

A shutter speed as low as 1/25th second can be used if the right instant is chosen for firing the shutter. At that speed, and with fast panchromatic material, the lens can be stopped down far enough to bring the nest and its surroundings into sharp focus.

In shady locations—or for walking at night—synchronised flash may have to be used. This should preferably be the flash bulb type because the hum from the charging circuit of an electronic flash is enough to keep many birds away And since the reflector will have to show outside the hide, it should be left in position for some days beforehand—covered with a sheet of transparent plastic—for the bird to get familiar with its presence in the neighbourhood of its nest.

BIRDS IN THE OPEN

Stalking birds with a camera in the open country is very much of a gamble; as a rule, the birds see the photographer long before he can come within photographing range. But most of the difficulties of this branch of bird photography can be overcome by attracting the birds with a suitable bait, particularly in winter when other food is scarce.

Garden birds can be tempted to come to a bait of suitable food placed on a bird table or wherever is the most convenient place for photography. Robins come to mealworms or cake crumbs, blackbirds to soaked bread or raisins; the tit family will cling to a hanging feeder containing nuts. The thrush species—field-fares, redwings, and mistle—thrushes—can be tempted with wild berries. The berries should be collected in the autumn and saved until the birds have stripped the hedgerows.

Large birds of prey like kites, buzzards, ravens and crows can be attracted by carrion such as a dead rabbit, pegged down to prevent it from being carried away.

All these forms of baiting ensure that the bird will remain in one place long enough to be photographed. It is only necessary to set the camera up in a hide and wait for the subject to appear. The hide should be erected several days in advance to give the birds time to get used to it.

Equipment. Any camera that will take a long-focus lens is suitable, but the miniature has many advantages if the bird has to be stalked. Where a bait is used to attract the bird, one very successful technique is to set up the camera on a tripod, focus on the bait, and then operate the shutter from a distance by remote control. With this technique any sort of camera will do. A suitable type of control that can be bought quite cheaply consists of a length of fine PVC tubing with the shutter release plunger at one

BIRD TABLE. The table is set-up outside window at the right height. Crumbs attract the birds for feeding. The camera is hidden behind a curtain with a hole for the lens.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

PYLON HIDE. To photograph birds in their nests in trees, pylon hides may have to be used. These may be as high as 60 feet. Strong cables keep the structure steady.

end and a press bulb at the other. If the camera is to work close to the bird, the spot should be baited for some days beforehand and a wooden box with a lens hole in the front should be left at the camera position. When the birds get accustomed to feeding in front of the box—which they will do in a day or so—the camera can be set up inside and shooting can start.

Exposure. The shutter speed to be used for birds in flight varies according to the direction of movement. A bird flying across the field of view and less than 20 feet away may need an exposure of 1/1000 second, but the same bird flying towards the camera could be photographed with a much lower shutter speed.

At the same time, the size of the bird has a bearing on the permissible shutter speed. As a rule, the smaller the bird, the faster it beats its wings and the higher the shutter speed needed.

The high speed of electronic flash is useful to arrest the wing action of birds. Use an aperture and flash intensity which allows a certain amount of daylight to be recorded in the background. When working from a hide it is not easy to judge the moment of exposure as the bird flashes past the small space covered by the lens; a fraction of a second either way makes all the difference between success and failure.

Radio Remote Control. An elaborate, but extremely successful method of photographing shy birds in close-up makes use of both radio and photo-electric equipment. The camera is set up near the bird's nest or a bait and either camouflaged or left in position long enough for the birds to ignore it. A photo-cell-operated shutter release and recycling device are coupled to the camera in such a way that when the bird crosses the point focused by the camera lens it releases the shutter and—if conditions require—fires a synchronized electronic flash. The equipment is switched to ready or switched off by a radio relay triggered by a small transmitter at the operating point. This is to economize in the local battery power while waiting for the bird to arrive. The photographer can be stationed as much as a quarter of a mile away—far enough to avoid disturbing the bird. He watches the scene through binoculars or a telescope and switches the circuit on only when he sees a chance of a picture. O.G.P.(F.P.)

BISCHOF, WERNER, 1916–54. Swiss photographer. After World War II, travelled for leading illustrated papers throughout the world. Killed in car crash in the Andes 16th May 1954 while working on a picture story on Peru. Several books of his photographs were published.

BISSON, AUGUSTE ROSALIE, 1826–??. French daguerreotype portrait photographer in Paris from 1841, when he and his brother opened a studio. During 1850s they became leading architectural photographers and equally noted for their Alpine views. July 1861 Auguste Bisson was the first to photograph from the summit of Mont Blanc. The expedition lasted three days and twenty-five porters were needed to carry the equipment for the wet collodion process. Gave up photography after the introduction of carte-de-visite views which reduced the demand for large prints.

BISSON, LOUIS AUGUSTE, 1814–??. French daguerreotype portrait photographer in Paris from 1841, when he and his brother opened a studio. During 1850s they became leading architectural photographers and equally noted for their Alpine views. They gave up photography after the introduction of carte-de-visite views which reduced the demand for large prints.

BITUMEN. General name of a group of mineral hydrocarbons. Only one form is of interest to photographers. This is the solid bitumen known as asphalt.

BITUMEN GRAIN PROCESS. Early printing process from which present-day photogravure was developed. The copper plate on which the image is etched is first dusted over with finely separated grains of bitumen. The plate is then heated to make the grains adhere during the etching process which follows.

A sheet of carbon tissue, exposed behind a positive transparency of the subject, is transferred to the surface of the copper plate and "developed" with hot water as in the carbon process. The plate is then etched with ferric chloride beginning with strong and then successively weaker baths which attack the copper in proportion to the thickness of the developed

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

gelatin print. After etching, the plate bears an impression of the image, deep in the shadows, and shallow in the highlights. This impression is covered with minute heterogeneous points of unetched copper where the surface has been protected by the grains of bitumen.

When the plate is inked and wiped, these points prevent the wiping action from removing the ink from the hollows forming the image. In this state, the inked image is printed by pressing it into contact with damped paper.

The bitumen grain process lends itself to a number of methods of control in the hands of the artist or craftsman. For this reason it is still used for individual work and for limited editions of fine art reproduction. F.H.S.

BLACK BODY. Theoretically perfect source of radiant energy.

The conception of such a hypothetical reference source is found useful in stating the spectral composition of light, or, in photography, its colour temperature.

When a solid substance is heated, it glows first dull red, then brighter red, and finally white. Discounting any light reflected from the surface, the energy distribution of the radiation emitted by the substance depends on the temperature to which it is heated. This is completely true for a black body—i.e., one which reflects no light falling on it.

In experimental physics such a black body is obtained by taking a hollow metal sphere and cutting a circular opening in one side. Owing to the shape of the body, all light entering the opening is absorbed inside the sphere and virtually none emerges again. This aperture is therefore black—i.e., the "black body" and on heating the sphere the light emerging is solely composed of radiant energy due to the heating.

The spectral composition of any incandescent light source can be stated in terms of the absolute temperature at which a black body emits rays of the same wavelength distribution. This temperature is referred to as the colour temperature of the light.

Apart from the above mentioned sphere there is no such thing as a perfectly black body; all substances reflect a certain amount of light which mixes with that emitted on heating. So the spectral composition of the light they emit is not absolutely proportional to their temperature. In many cases, however, the discrepancy is not serious.

See also: *Colour Temperature.*

BLACKING. Many formulae have been published in the past for making up paints and dopes for blacking the inside of cameras, lens hoods and lens tubes, dark slides, and enlarger bellows. Nowadays, however, there are preparations available for a shilling or so that dry in a few minutes and leave behind a dull black anti-reflection coating. It is always easier and cheaper to use the ready-made product.

The same holds for external blacking for which it is almost always better to use one of the brushing cellulose finishes than to try something home-made.

Those photographers who make their own equipment and accessories, however, often need to blacken metal parts that have to be handled. In this case chemical blacking is often better than applying one or more coats of paint. The following methods will be found satisfactory:

Brass. Make a solution of copper nitrate by dissolving 1 ounce of copper foil or turnings in 2 ounces of nitric acid (in open air). Clean the brass with emery cloth and cover it with the solution for 2 minutes. Now lift the part out with a wire hook and hold it over a blue gas flame. In a few moments a fine black coating will cover the surface. Repeat the process several times to build up a thick enough coating.

Aluminium. (1) The easiest way to blacken aluminium parts is to rub them bright with emery cloth, dip them in linseed or olive oil, and then heat in a gas flame to turn the oil into a film of black carbon. This type of finish tends to leave glazed patches and it does not stand up very well to handling.

(2) A more robust finish can be given like this: dissolve 1 part of arsenious oxide and 1 part of ferrous sulphate in 12 parts of concentrated hydrochloric acid. Add the solution to an equal volume of water (do not add the water to the acid). Clean the part with emery and immerse in the solution until it turns black. Wash and dry.

The finish can be given a gloss by rubbing lightly with linseed oil.

Iron and Steel. Ferrous metals can be blackened in the same way as aluminium (2) above.

BLACK LIGHT. Black light is the name for ultra-violet illumination when it is used to make objects visible in the dark. The objects are treated with a dye or pigment which fluoresces under the ultra-violet radiation.

The source consists of a mercury arc or other suitable light screened by a filter (e.g., covered with a lacquer) which cuts out all the visible rays but allows the ultra-violet through.

It is used in theatrical transformation scenes, and for publicity and advertising.

paper 1850. Founded at Lille the first photographic printing and publishing firm 1851. Blanquart-Evrard's technique of developing prints, instead of the slow business of printing them out, speeded up the mass production of prints for sale, and the publication of a large number of books and albums illustrated with original photographs.

BLEACHING. Converting a silver image (negative or positive) into a more or less colourless silver compound, such as silver chloride, bromide, iodide, or complex salts containing chromates, ferrocyanides, etc., of other metals as well. Bleaching forms the initial stage of a large number of toning processes for transparencies and prints (where the additional metal compounds often produce the colour of the toned image); as well as of many intensification methods.

Other applications of bleaching are in the formation of gelatin relief images and matrices for various control processes, and reversal processing of black and white or colour reversal materials.

BLEACH-OUT PROCESS. This is a method for making drawings by going over a photographic image in ink or pencil and afterwards removing the image by chemical bleaching. The photograph should preferably be a fairly pale print of a clearly outlined subject. The artist first draws over the outlines of the subject in either pencil or water-proof ink.

Two baths are used in the bleach-out process. The first is the bleacher; it consists of flake iodine dissolved in a solution of potassium iodide (about ¼ ounce of each to 5 ounces of water). The second is a normal fixing bath for prints; it may be acid or plain hypo.

The print is first immersed in the bleacher until the image disappears. It is then rinsed in running water and transferred to the fixing bath. After some time, the slight discoloration clears and leaves the drawing on a white background. The paper is then washed and dried in the usual way.

Line drawings for reproduction can be made easily and quickly by drawing over a blue print made from the photographic negative. When the composite image is photographed in the process camera, the blue does not reproduce.

See also: *Sketch photograph.*

BLISTER. Blemish on negatives and prints caused by bubbles of gas or liquid trapped under the surface of the emulsion. The bubbles may be formed either in the emulsion layer or between the emulsion and the support. Blistering occurs on films, plates and paper prints, and the cause can be diagnosed according to whether the blisters appear after development, fixing or washing.

Blistering During Development. When plates are developed at a high temperature the gelatin may swell and leave the support. Where this happens around the edges, it causes frilling of the emulsion; where it happens inside the margins it causes blistering. This type of blister can be avoided by hardening the emulsion before development—e.g., with an alum hardening bath or a 10 per cent solution of formalin. Once formed the blisters may disappear if the material is immersed in methylated spirit after washing and then dried off normally.

Blistering after Development. This is generally the result of transferring the sensitized material from a developer containing carbonate to a strongly acid stop bath or fixing bath. The resulting chemical action generates carbon dioxide which may collect in bubbles in the emulsion. Absence of hardener in the fixer or the use of a fixing bath much colder than the developer makes matters worse.

The remedies are: to rinse the material thoroughly after development; to use a hardening and fixing bath; and to keep the temperatures of all baths within two or three degrees of each other.

Blistering after Fixing. Water blisters may form on the surface of the material (more especially on prints) during washing immediately after being fixed in a strong fixing bath. The washing water penetrates the gelatin faster than the fixing solution can escape and detaches the emulsion from the support. Once the emulsion has been loosened in this way it is very difficult to get it to adhere after the water has dried out. Local damage to the emulsion —e.g., by creasing or handling with warm fingers—increases the likelihood of blisters.

Paper that is carefully handled and fixed in a hardening fixer of the correct strength very rarely suffers from this cause.

Blistering after Washing. Very cold washing water containing an excess of dissolved air (as most high pressure main supplies are likely to do) is another cause of blistering. In this case the trouble appears after washing and results from air bubbles liberated from the water as it warms up to the temperature of the atmosphere.

The remedy here is to allow the water to stand for some time and then to wash in successive changes.

Modern sensitized materials will stand a surprising amount of ill-treatment without blistering, and if they are handled with normal care and processed according to the maker's recommendations the risk of trouble on this score is negligible. F.P.

BLOCK. Name for mounted line and half-tone plates, and stereos and electros used for letterpress printing.

See also: *Photomechanical reproduction.*

BLOOMED LENS. Lens which has had one or more of its air/glass surfaces coated with a tin film of metallic fluoride to reduce the amount of light lost by reflection.

See also: *Coated lens.*

BLOW UP. (Slang.) Expression sometimes used to describe the enlarging of a negative; can also refer to the enlargement itself.

BLUE PRINT. Print made by the ferro-prussiate process. So named because it gives a white image on a blue ground. Invented by Sir John Herschel, 1842, and named by him Cyanotype.

See also: *Document copying.*

BLUR. Lack of definition in a negative or positive, caused by misfocusing or by movement of the image during exposure.

See also: *Faults.*

BODY RELEASE. Shutter release button or lever mounted on the body of a camera instead of on the actual shutter assembly.

BOGISCH, A. 1857–1929. German chemist. Worked at the Hauff factory at Feuerbach near Stuttgart. Discovered in 1893 the new developers metol, amidol, glycin, ortol.

BOISSONNAS, FRED, 1858–1947. Swiss professional photographer in Geneva; took over father's portrait studio 1888. Also made pictorial photographs for exhibition. Obtained first successful photographs of Mont Blanc from Geneva with telephoto lens, 1891, on orthochromatic plates manufactured by himself and his brother Edmond. Boissonnas took for Lord Napier thousands of views in Greece from 1902 onward, and was commissioned by King Fuad to do similar work on Egypt.

BOLTON, WILLIAM BLANCHARD, 1848–99. English amateur photographer in Liverpool; editor of *The British Journal of Photography* 1879–85. Associated with B. J. Sayce in the introduction of collodio-bromide of silver emulsion, 1864, but admitted, 1873, that Sayce alone was responsible for the invention. 1874, published an important improvement—a washed collodion emulsion process.

BOOKS ON PHOTOGRAPHY

Books on photography are as old as photography itself; Daguerre's own handbook on his technique was published in the same year as his invention.

To-day the literature of photography would fill large libraries. The library of the Royal Photographic Society contains 6,000 volumes and it does not claim to be complete even in respect of publications in the English language.

Only a very small proportion of these books consists of original works in the sense of containing information not available from alternative sources. Just as in literature on other subjects there is a large amount of duplication, of mutual borrowing and of pretension to knowledge.

The ideal book on photography should have as its author a person of sound technological training, practical experience, methodical mind, writing ability and some visual imagination. Such authors are rare. Many books are written by people who lack these attributes and are either too young or too old for the task. The reason for this is that experts of exceptional ability at the height of their career can seldom spare the time to pursue literary sidelines.

There is, however, an effectively compensating factor provided by the selective influence and the editorial resources of experienced publishers. It is by no means accidental that the best books on photography are published, in most countries, by a few specialist publishers, whose imprints serve as a reasonably reliable guide to the reading public.

Elementary Textbooks. The average amateur rarely needs an extensive library, but any purposeful and satisfying photographic activity warrants the study of some elementary introduction to the subject to avoid the disappointment of haphazard and accidental results. There are scores of elementary books on the market and the safest way of choosing among them is to be guided by the degree of their proven popularity. In view of its reprint record since its first publication W. D. Emanuel's *All-in-One Camera-Book* appears at present to be the most widely read independent "first book" on photography in the English language.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

Manufacturers' introductions to photography vary a great deal in size, scope and purpose. Their presentation is often more lavish than independent publishers' products. Technically they are very reliable and authoritative within the limits defined by the individual manufacturer's interests and policies.

Comprehensive Works. Books on photography suited to training professionals and serving other serious students are less numerous than they used to be. The older generation of authors who could command and transmit encyclopedic surveys of photography as a whole is no longer with us and keeping their works up to date has proved an almost insuperable task.

Attempts at replacing individual works of this order by comprehensive symposia assembled from the work of a number of experts suffer as a rule from serious editorial difficulties in co-ordinating the material across varying levels of outlook and methods of approach.

The British *Manual of Photo Technique* avoids the difficulties inherent in multi-authorship by splitting up the subject into a series of smaller but self-contained volumes of which, so far, twelve have been published: H. J. Walls' *Camera-Technique*, Arthur Cox's *Optics*, R. H. Cricks's *Illumination*, W. F. Berg's *Exposure*, C. I. Jacobson's *Developing* and *Enlarging*, O. R. Croy's *Retouching*, J. H. Coote's *Colour Prints*, C. L. Thomson's *Colour Films*, P. Jenkins' *Colour Separation Negatives*, K. C. M. Symons' *Stereo Photography*, L. Lobel's and M. Dubois' *Sensitometry*.

Special Techniques. The application to definite subjects like portraiture, scenery, natural history, etc., is covered by many useful books. In these fields of specialization the reader has a reasonable chance of finding the book he wants by basing his choice on the author's reputation or on his skill as a photographer as evidenced in his illustrations.

When selecting a book on special techniques —e.g. lighting, photomicrography, medical photography, etc.—the frequency of its reissue is perhaps the most truthful guide to its reliability and completeness. No sizable work of this kind can hope to be entirely free of misprints or omissions at its first publication and so if there is a comparable choice between a book that is well established and one where the merit appears to lie in novelty, the established work is likely to be preferable provided the date of its last re-editing is reasonably recent.

Books which purport to pass on the secrets of photography as an Art form are now less frequently published than in the past. They have, in fact, never been particularly successful; the technically minded reader may be eternally thirsting for further knowledge but people with predominantly artistic interests are apt to be too individual to wish to follow someone else's approach, particularly from books.

The advent of several high performance cameras during the last few decades has also led to the appearance of some fairly ambitious volumes which serve as complete textbooks based on the techniques of the particular camera and its accessories. The genuine usefulness of such works is beyond doubt when they are devoted to sufficiently mature instruments and their authors are in the position to pass on specific and independent information. This is, however, by no means always the case. Some manufacturers are quick to encourage any further addition to the literary background of their merchandise and so the potential reader is often faced with a bewildering assortment of competent technical advice, diluted journalistic hand-outs and glossy pictorial puffs. But here, as always, the buyer can safely let his choice be guided by the standing of the publisher, the reputation of the author, and the number of recent reprints of the work. As the growing pressure of competition propels manufacturers into continually overtaking each other with new models of their products (just as the makers of automobiles do) books on cameras have to be very recent indeed to be fully useful to the owner of the very latest model of that particular camera.

Scientific Books. The tendency to specialize within a wide subject has become most marked in the scientific field. Almost the only modern book to offer a wide and yet penetrating view of the subject as a whole is *The Theory of the Photographic Process* by C. E. Kenneth Mees. This work is the product of a brilliant creative mind and mature experience furnished with the resources available only to the research laboratories of a giant organization for manufacturing photographic materials. Scientific publications emanating from such centres are among the most authoritative and valuable contributions to the photographic libraries.

We have today a young and very populous generation of scientists who record the results of their research in short papers on some narrow sector of specific subjects rather than in self-contained monographs. The best all-over view of their work was presented periodically in the volumes of *Progress in Photography*, an international survey and summary which is now replaced by the quarterly *Perspective*.

Originating at the same source *The Focal Library* now serves as a central pool of information on the science and technology of photography, cinematography, image and sound recording. It covers research, manufacturing processes and special applications of both by teaching texts, symposia and monographs. The principle language of the library is English including translations from other languages, notably Russian and German; symposia are multilingual. The Library is governed by an Editorial Board of leading experts in high academic and other scientific positions from ten countries.

General Reference Books. Among general reference books offering a wide variety of photo-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

graphic data the American *Photo-Lab Index* is the most ambitious and correspondingly elaborate publication. Leading manufacturers of photographic materials in Great Britain, U.S.A., Germany, Belgium, etc., publish their own data books which offer the advantage of the most authentic and up-to-date information on their own products.

Amongst annual publications of reference the *British Journal Photographic Almanac* (first published for the year 1860) holds undisputed seniority and is known all over the world, chiefly among professionals. *The Photo-Amateur's Pocketbook* is for more popular use.

Trade directories are provided in Great Britain by *The Photographic Dealer's Pocketbook* and in the U.S.A. by *The Photo-Dealer's Directory*.

Pictorial Collections. Pictorial annuals are found in every country but only few of them stay. They are expensive to produce and so have to rely on the fickle support of advertisers. Among the best known are the British *Photography Year Book* and the *U.S. Camera*, both representing a revitalized pictorialism following patterns of contemporary illustrative and commercial photography.

Books by photographers are not necessarily on photography and their success or otherwise is no indication of their importance to readers on photographic matters. Cecil Beaton's semi-autobiographical books, for example, have never failed to attract a public, but this has little to do with the fact that their author happens to be a photographer, among other things.

Fine volumes devoted to the work of individual photographers are a publisher's nightmare. They are gladly looked at but rarely bought—unless devoted to a specific subject which commands attention in its own right.

Inexpensive Publications. Photographic publishing has its "paper backs" and their impact is equally impressive. For a few pennies these little books provide straightforward answers to practically any problem "the man in the street" using a camera may encounter. Their influence in recent years has been responsible for turning millions of snapshotters into enthusiastic and reasonably successful amateur photographers. For these millions the *Focal Photo Guides* and *Viewfinder Books* and other series fashioned on their example act as an unfailing source of commonsense information and assistance.

The *Camera Guides* are a closely related type of publication. These books have improved on the function of the manufacturers' instruction literature about specific cameras by being more informative, sometimes more clearly written and certainly more impartial when it comes to dealing with the limitations as well as the scope of the camera in question. They are constantly kept up-to-date. A.K.-K.

See also: *Literature on photography; Periodicals; Training and education in photography.*

BOOM LIGHT. Light source attached to the end of an adjustable boom to give it a wider range of horizontal movement than is possible with a simple telescopic stand. A boom light enables a subject to be lit from above or behind, without getting the light-stand in the picture.

See also: *Light supports.*

BORAX. Sodium tetraborate, weak alkali in fine-grain developers.

Formula and molecular weight: $Na_2B_4O_7 . 10H_2O$; 381.

Characteristics: White crystals or crystalline powder.

Solubility: Slightly soluble in water at room temperature; fairly soluble in hot water.

BORDER. Margin of the print, which may be left white, printed black, or treated in a number of other ways to suit the subject. A white border is the most common, although prints trimmed down to the picture area without leaving a border are also popular.

See also: *Masks; Paper holder.*

BORIC ACID. Boracic acid. Used in hardening fixers containing potash alum—extends the hardening life of such fixers; also in certain buffered fine-grain developers.

Formula and molecular weight: H_3BO_3; 62.

Characteristics: White crystalline powder.

Solubility: Slightly soluble in water at room temperature.

BOTANY

Botanical photography is essentially concerned with making accurate records of plant life. In every branch of botanical study and experiment the camera supplements the notebook of the naturalist and scientist and it has therefore a very wide range of applications. The principal fields are: life histories of individual species, comparative studies, plant variation in relation to environment, plant structure. Subjects range from high plants to microscopic grains of pollen, fungus spores and the like.

In general there are three ways of photographing plants: growing in their natural surroundings, complete in the laboratory, and dissected in the laboratory. Each class of photograph poses different problems and to some extent calls for different equipment. The first two classes require normal photographic equipment, the third class usually involves photomacro- and micro-graphic apparatus.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Equipment. Accurate detail in the final print is essential in such scientific records, and very often the negative will be printed as a lantern slide which will be greatly magnified in projection. So in general the largest convenient plate camera is preferred—e.g., a quarter-plate or at least a 2¼ × 3¼ ins. stand type. There must in any case be provision for focusing by screen, and the camera must have a double extension for taking close-ups of small plants. A reflex camera is suitable so long as it has some means —e.g., extension tubes—of providing the necessary extension. And since focusing extremely close-up subjects is critical, a focusing magnifier is essential. There is very little need for a wide aperture lens in botanical photography because the normal practice is to stop well down—to *f*11 or *f*16—to get the maximum depth of field. Occasionally, however, it is convenient to be able to use differential focusing to separate the subject from the background. There are times, too, in a wind, or if photographing an uprooted specimen that is wilting, when it is necessary to use a wide aperture and an instantaneous exposure. So the lens should have a maximum aperture of about *f*4·5. Colour materials are being increasingly used for botanical records, making it necessary for lenses to be fully colour corrected.

Ideally there should be a selection of lenses to cope with the wide variety of subjects and conditions—e.g., a normal lens for routine exposures; a long focus lens to give a big image with good perspective of small subjects *in situ*; a short focus lens for macro-scale photography of small thin objects where perspective is unimportant, such as for sections; a wide angle lens for confined situations, and a telephoto lens for distant shots of inaccessible specimens. If only a single alternative is permissible, it should be a long focus lens giving about one and a half times the image size of the normal lens.

Since time exposures are normal, a really rigid tripod is necessary. The tubular telescopic type used without the legs extended is generally satisfactory. In addition the tripod must be equipped with a tilting head which allows the camera to be pointed down at any angle including the vertical. A suitable tilting platform can be made from two pieces of ½ in. thick plywood hinged at one end to open and shut like a book. A length of slotted brass attached to one half engaging with a thumbscrew on the other enables it to be locked at any angle. One of the hinged pieces is attached to the top of the tripod and the camera is fastened to the other with a bolt screwed into the tripod bush.

As far as possible, the tone values of the subject should be natural since the photograph is intended to give an accurate impression of the colours or their monochrome equivalent. Normally only a pale green correction filter should be used with medium speed panchromatic material. Where a contrast filter is used to emphasize certain features, the fact should always be noted on the print or included in the caption if the picture is published.

SPECIMENS IN THE FIELD. For a detail close-up of a plant set up the camera at the same level as the subject, and arrange a background of plain light grey paper behind the plant to be photographed. This also screens the plant against air movement.

The most suitable form of sensitized material for exposures in the field is a medium speed or soft gradation panchromatic plate. In the laboratory—and in particular for macro and micro work—it is sometimes better to use a slow panchromatic plate for the sake of the crisper contrasts.

Lighting. Where the subject is out in the open, daylight is the obvious form of lighting, but much botanical photography must be done in woods and forests or under hedges and banks—where the light is feeble and exposures would be unduly long. Under these circumstances it is better to rely on a lightweight portable electronic flash. This need not exceed 30 to 50 joules because the subject will usually be small enough to be covered by a flash two or three feet away. Flash has the added advantages that it arrests any movement due to wind or wilting and can be directed from any angle to conform with the camera viewpoint. (If the sun shines from the wrong angle, the photographer may have to wait a long time for it to move around.)

Where the weight of an electronic flash is a disadvantage, and only one or two exposures are contemplated, ordinary bulbflash may be used.

Field Work. Some time is always spent in finding a specimen that is typical—not necessarily the largest.

The main object of photographing a specimen in the field is to show it in its natural surroundings, so there is no point in choosing a subject that happens to have taken root in uncharacteristic terrain. For the same reason the subject must not take up the whole of the picture space to the exclusion of the setting. Under these circumstances it is not always easy to emphasize the subject—e.g., by differential focusing or lighting—without giving an un-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

CAMERA ROSTRUM. For laboratory shots with simple apparatus the specimen is laid out on a glass plate above a plain background. The camera is mounted squarely over the glass.

natural impression. Often the best compromise is to take two photographs: one a straight record of the plant in its setting, showing both sharp and in their normal tone values, and the other a close-up of the plant to show its details. Plants more than 6 ins. or so high are generally best shown close up against a plain background of light grey paper.

Plants should always be photographed with the camera down on their level, and not looking down from normal eye level. White paper reflectors or a fill-in flash are generally necessary to light the lower surfaces of the plant because these receive little or no natural reflected light and are apt to come out solid black.

In pictures of fungi it is important to show the underside of the cap, so one good specimen is always pulled up and laid alongside the others to show the gills or tubes.

Laboratory Work. When a specimen is photographed in the laboratory it is with the object of showing its shape, colouring, root development and general proportions. It is most conveniently photographed spread flat out with the camera looking down on it. In this case the specimen chosen should be a single complete growth, freshly dug up and with the earth washed out of the roots. The plant is then laid out on a clean glass plate supported horizontally above a plain sheet of neutral coloured paper. Both the plant and the background are lighted to give the required contrast—i.e., showing the specimen either darker or lighter than the background.

Some specimens — delicate flowers and orchids in particular—start to wilt rapidly as soon as they are prepared for photographing, and the heat from normal electric lights makes matters worse. The result is that the specimen looks tired and, during a time exposure, leaves and petals may even show some movement. In such cases, use an electronic flash with a good reflector to fill in the shadows and, if possible, a second flash directed on to the background.

The subject may also be photographed in daylight near a window with the background paper sloped to catch the light and a hand mirror used to reflect light into the shadows.

Small Subjects. Much of the laboratory work is concerned with making records of dissected plants, seeds, pollens and such-like small subjects. Some plant sections are large enough to be taken by normal close-up photography, but cross-sections of flower stems, individual blooms, seed-pods and leaves call for macro-photographic techniques. Such pictures can, however, still be taken with the normal camera and lens equipment by adding extra extension tubes or bellows and using a short focus lens in place of the normal camera lens.

Further down the scale of sizes there are the seeds, pollens and spores that call for photomicrographic equipment. The technique here is simply normal photomicrography and differs in no other basic way.

The photographer who has no special equipment for making highly magnified photographs can, within limits, make do with his enlarger. It is a simple matter to substitute a mounted specimen for the negative in the enlarger and project it in darkness on to a plate laid emulsion side up on a black card on the enlarger baseboard. In this way enlargements can be made up to 20 ×. The negative made in this way can be further enlarged, although the normal camera or enlarger lens cannot be expected to give results equal to those of a properly corrected microscope objective designed specially for this work. H.J.H.

See also: *Biology; Close-ups; Flowers; Gardens; Macrophotography; Photomicrography.*
Books: *Camera Close-up*, by O. R. Croy (London).

BOTTLES. Photographic solutions are most conveniently stored in glass bottles with rubber stoppers. Glass stoppers tend to stick unless they are greased regularly, and in the darkroom, grease on anything that has to be handled is a nuisance. Cork stoppers are unsafe because they are attacked by many photographic solutions. Concentrated acids that are usually stored in glass-stoppered bottles are not normally used in photography.

Ribbed bottles are used for poisons, amber or brown for solutions that deteriorate under the action of the actinic rays, and clear glass for most other liquids. Concentrated developers are always sold in brown glass bottles.

The commonest sizes are 10 ounce (284 cc.) or half-pint; 20 ounce (568 cc.) or pint; 40 ounce (1,136 cc.), or quart; and 80 ounce (2,272 cc.) or Winchester quart.

The labels on bottles should be painted over

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

with clear cellulose lacquer or covered with transparent tape to prevent them from being discoloured by the solution or washed off when the bottle is cleaned.

Polythene bottles are made in all the sizes normally used in photography. They are unbreakable, and unaffected by any of the chemicals used in ordinary photographic processing. They have a further useful property: being flexible they can be squeezed to exclude any air, if the liquid contents do not quite fill the bottle. This makes them particularly suitable for storing liquids which are oxidized easily—e.g. most photographic developers.

BOURNE, SAMUEL, 1834–1912. English photographer of Indian views. Took up photography in the mid-1850s and *c.* 1860 became a partner in the firm founded by Shepherd in Simla 1843 (later also in Calcutta). Bourne became famous for his photographs of the Himalayas taken on expeditions lasting several months and requiring up to sixty porters to carry the wet collodion equipment and other baggage. 1868, photographed at an altitude of 18,600 feet—a record held until 1880.

BOX CAMERA. The box camera is the simplest and cheapest type of camera. It is mainly intended for people who want to take snapshots in good light and who do not know —or want to know—a lot about photography. In its traditional form, it is simply an oblong or square box fitted with a very elementary lens, shutter, and viewfinder, and some means of registering and winding a paper-backed roll film.

Modern box cameras are usually more streamlined, resembling miniature cameras in appearance. In recent years designers have made extensive use of the possibilities of styling offered by the simple design and by the utilization of moulded plastic body components.

Traditionally box cameras used to take $2\frac{1}{4} \times 3\frac{1}{4}$ inch (6 × 9 cm.) or $2\frac{1}{4} \times 2\frac{1}{4}$ inch (6 × 6 cm.) pictures on size 120 roll film. A more modern trend is the box camera taking 16 exposures $1\frac{5}{8} \times 1\frac{5}{8}$ inches (4 × 4 cm), again on size 120 roll film, yielding greater film economy (even though part of the film area is wasted). This has become popular with reversal colour films, especially as the $1\frac{5}{8} \times 1\frac{5}{8}$ inch format is suitable for mounting in 2 × 2 inch super slide mounts.

An alternative and still popular film size is 127, yielding usually 12 exposures $1\frac{5}{8} \times 1\frac{5}{8}$ inches (4 × 4 cm.). Other sizes also exist (for example 828 for 28 × 40 mm. images on unperforated 35 mm. film).

The Body. The box itself is generally made of plastic or of sheet metal, covered with leather or plastic. It is made to open so that the film can be inserted. There is one chamber to hold the full spool of film and another for the empty spool. Between the two chambers the film is led behind a metal aperture that frames the picture area. A spring-loaded pressure plate fixed inside the back of the box keeps the film pressed flat against the picture aperture.

BOX CAMERA. Feed and take-up spools are on each side of a cone, pulling the film across the rear opening. The front contains the lens, shutter, and a viewfinder.

With some designs the film plane is curved, so that the film is deliberately not allowed to lie flat. This to some extent compensates for the curvature of field of the cheap lenses employed.

The film is transported by turning a key or knob on the outside of the box. There is a window—and sometimes two—located in the back of the camera through which the frame numbers on the paper backing of the film can be read when winding on from one frame to the next. This window has a red or green filter in it to stop active light from getting to the film.

Lens. The lens in the cheapest box cameras is made of a single meniscus-shaped piece of glass. It is not corrected for any of the aberrations and has a single fixed stop that confines the light rays to the centre of the lens and gives it an aperture between *f* 11 and *f* 16. Some of the better types have doublet lenses with a maximum aperture of about *f* 8.

MODERN BOX CAMERA. Present-day popular box cameras are usually more aesthetically styled and they incorporate such features as a built-in flash gun. A, flash reflector. B, release. C, film transport. D, viewfinder. E, lens.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The most usual type of lens fitted has only one fixed stop, but some have two or three stops consisting of holes in a movable plate in front of the lens.

Some modern box models incorporate an exposure meter coupled to the lens aperture, so that the latter is automatically set by the prevailing light. Electric eye models of this kind still have only a fixed single shutter speed, but the exposure meter system directly operates movable plates perforated in a certain way to produce larger or smaller lens openings.

Focusing. There is no means of focusing on a typical box camera; the lens is set at a fixed distance from the film to give reasonably sharp negatives of everything beyond about 7 feet from the camera. More expensive types focus down to 3 feet. To do this the lens is made to slide or screw outwards in its mount.

Shutter. Box camera shutters are very simple affairs; they admit light to the film through a hole in a metal disc rotated by pressure on the shutter release lever.

Nowadays the shutter incorporates a set of contacts to synchronize the firing of flash bulbs with the full open position of the shutter. In some cases special flash guns are available which plug directly into the camera, without the need for a connecting cable between the flash and the shutter.

Some box cameras have the flash gun built in, with a miniature reflector in the front of the housing—above or to one side of the lens—taking miniature flash bulbs. A special compartment of the camera then takes the batteries for firing the flash. As an alternative the reflector may rise up from the top of the camera (and be collapsible) taking the smallest types of flash bulb. Box cameras with a built-in electronic flash unit have also been proposed.

Viewfinder. The viewfinder on the smallest box cameras is usually of the direct-vision type, either frame or optical and on larger sizes, a reflex type. In such cameras the picture in the viewfinder is often the same size as or only slightly smaller than the negative.

In spite of its simplicity the box is capable of taking photographs of a high standard.

BOYLE, ROBERT, 1627–91. Irish scientist, son of first Earl of Cork. One of the founders of the Royal Society; became President in 1680. Discoverer of the law (governing gases) which bears his name. Described the darkening of silver chloride when exposed to light, but attributed it to air. Devised a camera obscura.

BRADY, MATTHEW B., 1823–96. American portrait photographer; opened a daguerreotype studio in New York 1844 and in Washington 1847. Photographed many famous Americans and formed a National Photographic Portrait Gallery. In 1861 he organized the photographic documentation of the Civil War by teams photographers in his employment, the m important of whom was Alexander Gard The undertaking impoverished Brady and was obliged to sell his collection to the U Government in 1875. Biography by Ja Horan (New York, 1955) and by Roy Mere (New York, 1946).

BRAGG, SIR WILLIAM HENRY, 18 1942. British physicist. With his son, William Laurence Bragg (born 1890), recei the Nobel Prize in 1915 for fundamental w in X-ray crystallography.

BRAUN, ADOLPHE, 1811–77. Alsat textile designer, photographer and founder the firm *Braun et Cie* in Dornach and Pa Started as a daguerreotypist *c.* 1842 and beca widely known in the 1850s for his photogra of flowers, and in the 1860s with his inst taneous street views of Paris and views Switzerland. Introduced into France Swa carbon process, particularly for the reprod tion of old master paintings.

BREW. (Slang.) Developer, usually hor made, of an unorthodox type, or more jo larly of uncertain age.

BREWSTER, SIR DAVID, 1781–1868. Scott scientist. Friend of Fox Talbot, introduc D. O. Hill to R. Adamson, 1843. Perfected refracting stereoscope, 1849, which was co mercially introduced two years later. W it began stereoscopic photography, in which first the pictures were taken by moving camera, or by two separate cameras. Brews suggested the twin-lens stereo camera, 18 the prototype of which was not construct until 1853.

BREYER, ALBRECHT, 1812–76. Germ physician, born in Berlin but living in Belgiu Invented in 1839 reflectography (Breyertype i.e., reflex copying by exposing a silver chlori paper through the back of the printed pa without a camera. His method was later p fected in the Playertype and Manul processes

BRIEF EXPOSURE (B). Term for a ti exposure in which the shutter remains op only while the shutter release is held dow Sometimes also called a bulb exposure.

BRIGHT-LINE FINDER. Optical viewfind which shows a white frame within the field view, outlining the actual view taken in by t camera lens. The frame may incorpora parallax correction marks or may even coupled with the focusing movement to co pensate automatically for parallax. On camer

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

with interchangeable lenses the finder sometimes shows several bright frames alternatively or simultaneously to indicate the fields of view of different focal lengths.

See also: *Viewfinder.*

BRIGHTNESS RANGE. Term indicating the ratio of the brilliance of the extreme highlights to the darkest shadows of a scene or image.

See also: *Contrast; Contrast control; Exposure; Gamma.*

BRILLIANCE. Another name for luminosity, i.e., the intensity of light reflected from a surface (= incident light intensity × reflectivity of surface).

BRILLIANT FINDER. Reflex viewfinder fitted to many cheap cameras. It has a plano-convex lens instead of a ground glass viewing screen.

See also: *Viewfinder.*

BRITAIN

Photography as we know it today represents a technological triumph whose foundations were laid by many men working in many lands, all driven by the same compelling purpose, with minds actively searching for ways and means of achieving that common aim and each quick to seize upon new ideas and new discoveries that might bear upon the problem. This is the British part of the story.

Sensitized Materials. In 1802 there was presented at the Royal Institution of Great Britain a paper entitled, *An Account of a Method of Copying Paintings upon Glass and of Making Profiles by the Agency of Light upon Nitrate of Silver.* Its authors were Thomas Wedgwood, son of the famous Staffordshire potter, and Sir Humphry Davy, and in the work described they were following up the earlier experiments of J. H. Schulze who, 75 years earlier, had produced simple patterns on chalk, made light-sensitive with silver nitrate, and contained in a bottle. As far as we know, Wedgwood was the first to try to make pictures on a light-sensitive surface. The process had very limited utility because of the impermanence of the record—no means were known by which the image could be fixed—but it was the acorn from which the oak tree grew.

Wedgwood had little opportunity to take his experiments further; he died in 1805. Davy turned his attention to other matters and for a time no further progress was made in this country.

In France and elsewhere the daguerreotype did an enormous amount to stimulate public interest in these matters, but the next step in the straight line development of photographic techniques was again made by an Englishman, William Henry Fox Talbot, of Lacock Abbey in Wiltshire. Much has been written about the various dates on which Daguerre and Fox Talbot made their discoveries and published them, but the significant fact is that the daguerreotype, which made all the running at the beginning, was a branch development which by its nature could not fail to be superseded and eventually entirely eclipsed.

Fox Talbot was a country gentleman with exceptionally wide interests and a mathematician and botanist of great ability. While on holiday on Lake Como he attempted to make drawings with the help of the camera lucida and began to reconsider the use of the camera obscura which he had previously used for a like purpose. He wondered how he could make camera images permanent. On his return to England he began to experiment with paper treated with silver nitrate and found that paper treated first with sodium chloride and then bathed in silver nitrate was more sensitive to light. To render his results less fugitive, he "fixed" them in a strong solution of common salt or potassium iodide. It was not a completely satisfactory method but it enabled him to make records which could be kept for examination at a later date. At first, like Wedgwood and Davy, he was dealing with shadowgraphs in which lights and darks were reversed. But from such a print, waxed to make the paper transparent, he was able to produce another with lights and darks reversed again, which reproduced the original subject exactly. So the negative-positive system of photography came into being.

Wedgwood had tried without success to make camera pictures. Fox Talbot began his research in 1834 and in 1835 he succeeded in making a picture in the camera obscura—the famous *Latticed Window* of Lacock. In 1839 he read a paper to the Royal Society in London entitled *Some Account of the Art of Photogenic Drawing or the Process by which Natural Objects may be made to Delineate themselves without the Aid of the Artist's Pencil.* This paper appeared in the *Proceedings of the Royal Society* 1839.

In 1841 Fox Talbot patented the calotype process which employed development of a latent image based on the developing action of gallic acid, and he followed up with another patent covering fixation with sodium thiosulphate. But there were other inventors in the field at the same time. Gallic acid had been used by the Rev. J. B. Reade, a minister of the Church of England, as an accelerator before and during the exposure and he claimed also to have been the first (in 1837) to use sodium thiosulphate to fix the image. The fact that it was a good solvent of silver salts was discovered by Sir John Herschel in 1819 and he is generally

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

given the credit for the introduction of hypo as a fixing agent. He also suggested the use of the terms negative and positive in connexion with the new process.

In 1844 Fox Talbot began to publish *The Pencil of Nature*, a work in six parts containing twenty-four calotypes. This was the first book to be illustrated with actual photographs. Here, then, was the practical process employing a camera exposure of reasonably short duration, with development and fixation to give a stable negative image from which any number of positive copies could be made.

It needed only the close attention of other minds for improvement to follow improvement and for photography to become the practical process which we know today.

Paper is not a very good support for the negative material. It was clear that a transparent base such as glass would be better, but there had to be a medium in which the silver salts could be held and applied. Albumen had been used by Niepce de St. Victor, and collodion had been suggested by Gustave le Gray in Paris, but the practical realization of the collodion process must be credited to another Englishman, Frederick Scott Archer of Bishops Stortford, who published his method in 1851. Here was a process capable of excellent results, but cumbersome in that the sensitization had to be done on the spot with development following immediately after exposure. This was known as the wet collodion process and it survives in a limited fashion to this day. Collodion dry plates were manufactured and sold at home and abroad by Dr. Hill Norris of Birmingham in 1856, but they were very slow in speed.

Dr. R. L. Maddox made the next great contribution. He used gelatin as the medium for the sensitive salts and described his experiments in a letter to the *British Journal of Photography* in 1871. Following improvement by others the gelatin dry plates were faster than the wet plates and after exposure there was no need for immediate development. The latent image was reasonably stable. From that date progress has been rapid and continuous.

Silver salts are naturally sensitive mainly to radiations at the blue end of the spectrum, so the early photographic emulsions were less sensitive to yellow and red light. Then, in 1873, Herman Vogel, Professor from Berlin, discovered that a box of plates manufactured in England and containing a dyestuff to suppress halation had a band of sensitivity wider than the normal. It was some time before his observation was confirmed by E. Becquerel in 1874 and J. Waterhouse in 1875 and even longer before sensitizers were found which did not adversely affect the emulsion. Pioneer work in England was done by C. E. K. Mees and then Sir William Pope and Professor W. H. Mills in conjunction with F. F. Renwick during the first Word War when it was necessary to make good the loss of German supplies; later work by other British investigators resulted in the description of the merocyanines and in the general elucidation of the essential structure of all colour sensitizers. This was followed by new work on fog restrainers, stabilizers and developers—work which has recently culminated in the discovery of Phenidone—phenylpyrazolidone.

In the field of colour, Britain can claim the fundamental conception of the three-colour theory formulated by Clerk Maxwell, a Scot, and the first demonstration of successful additive projection by him at the Royal Institution in 1861 when he reproduced, even though somewhat imperfectly, the colours of a piece of tartan ribbon.

A great deal of work was done in Britain on the screen plate process by J. Joly, C. L. Finlay and others, leading to the use of the integral screen process for still and cine work.

In subtractive colour processes, three-colour carbro was developed by the Autotype Company and as a practical factory process under complete control in England by H. D. Murray, P. C. Bull and D. A. Spencer. One of the integral tripack processes now available originated and was developed in Great Britain.

The chemistry and physics of the processes of photographic emulsion-making are complicated and the principles have been elucidated only very slowly. In the same way the laws relating amount of exposure to the depth of image developed had to be discovered by patient experiment. The popular idea was that by varying the development, or by intensifying or reducing the image, tone relationships could be varied more or less at will. This conception did not satisfy Dr. Ferdinand Hurter, a Swiss chemist working in England. He had been induced to take up photography by his friend, Vero C. Driffield, an English engineer. They began to examine the problem of photographic sensitivity together, and the work became the classic example of brilliant research in the photographic field. On the 31st May, 1890, they read their paper, *Photochemical Investigations and a New Method of Determination of the Sensitiveness of Photographic Plates*, before the local section of the Society of Chemical Industry at Liverpool. After preliminary criticism this work was accepted and the H. & D. curve established as the guide to the behaviour of the photographic emulsion.

The Support. Glass was a fairly adequate support, so long as the photographic material was required in flat sheets, and its rigidity makes it still the most suitable base for a number of important purposes today. Where flexibility was called for, it failed and was supplanted by cellulose nitrate. This material was first produced in Birmingham by Parkes, and it later made practicable the provision of sensitive material in roll form—although Eastman's first roll film was in fact a gelatin emulsion on a paper base which was afterwards stripped.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

In the years 1888–90 William Friese-Greene, a fashionable London studio photographer, was using emulsion coated on strips of celluloid in his moving picture camera for which he took out the famous master patent in 1889; today, emulsion on film support has ousted glass from most fields other than graphic arts.

Celluloid held the field for many years as the universal support for flexible film, but its inflammability led to continuous work on slow-burning or "safety" supports and by now it has been almost entirely displaced.

For many years Britain lagged behind in the manufacture of film base, but just before the second World War a start was made by two British firms working in conjunction, which led to the production in this country of first-class film base in quantities commensurate with the requirements of the home market.

Special Processes. Side by side with the main photographic process there developed other methods of making pictures by light, many of them being evolved or improved in Britain.

In 1839 Mungo Ponton of Edinburgh made a light-sensitive bichromate paper. Fox Talbot knew of the work and realized that it was the size in the paper which was affected by the bichromate. By 1852 he was using bichromated gelatin and albumen in important pioneer work in photo-engraving.

In 1842 Sir John Herschel introduced the blue print or ferro-prussiate process which depended on the reduction of ferric salts to the ferrous state.

In 1864 Sir Joseph Wilson Swan patented the first practical method of pigment printing. He coated glass with collodion and then with pigmented gelatin. After drying he stripped off the film from the glass. Later he coated his pigmented layer direct on paper. After sensitization with potassium bichromate and exposure the surface was coated with indiarubber solution and then the unhardened gelatin and the original paper support were washed away. Another transfer was then employed to bring the image the right way round. Improvements were made by J. R. Johnson in 1868 and J. R. Sawyer in 1874.

Carbro, in which the hardening is brought about by means of a chemical reaction between the pigment paper and a bromide print, was a development by H. F. Farmer of a technique introduced by T. Manly in 1905, following up his Ozotype paper of 1899. The development of the three-colour carbro process has already been mentioned.

In 1873 William Willis invented platinotype, a rapid printing-out material containing salts of iron and platinum in which ferric iron was reduced to the ferrous state by the action of light. It was developed by immersion in potassium oxalate when the ferrous salt brought about the reduction of the platinum salt to metal. In 1917 palladiotype, a variant, was introduced by the same company.

In 1891 C. F. Cross, E. J. Bevan and A. Green introduced the primuline process, the first of the diazo-dye printing processes.

Eadweard Muybridge, whose series of photographs of people and animals in motion constituted one of the first steps in the development of cinematography, worked in America but he himself was English. Other notable British pioneers in this field were Friese-Greene and R. W. Paul.

Lenses. The achromatic lens was invented by an Englishman, W. Chester Moor Hall, in 1733, who had a few telescopes made for his own pleasure but did not publish his discovery. John Dollond demonstrated an achromatic prism to the Royal Society in 1758 and applied it to the construction of the telescope. W. H. Wollaston's meniscus lens, devised in 1812, was used by Fox Talbot and by Daguerre. One of the most famous lens-making firms in England was founded in 1830 by Andrew Ross, an instrument maker skilled in optics and the making of microscopes and telescopes. His son, Thomas, in 1841 made a doublet of two cemented achromatic lenses, and Thomas Davidson of Edinburgh made a symmetrical doublet the same year, but the intrinsic merits of these lenses were not appreciated at the time. Andrew Ross claimed to be the first to make achromatic single photographic lenses of two glasses only and he made for John Kibble of Glasgow a monster lens which had a clear aperture of 13 ins. and a focal length of 6 feet. The camera to which it was attached was mounted on wheels and drawn by a horse and it took a picture 36 × 44 ins.

In 1857 Thomas Grubb patented an achromatic meniscus lens, and in 1858 Thomas Sutton a symmetrical separated triplet.

John Henry Dallmeyer had married the daughter of Andrew Ross and set up on his own account in 1839. In 1858 he made lenses for Thomas Skaife's Pistolgraph camera, and in 1860 produced a rapid lens of the Petzval type which became known as the "baby" lens because it was so suitable for subjects in that class. In 1866 Dallmeyer patented an aplanat. H. L. Aldis came to him as a mathematician, so these three companies, Ross, Dallmeyer and Aldis, have long established associations.

After the introduction of the new barium crown glasses of the Schott glass factory at Jena the firm of Ross went on to make a variety of famous lenses including the Ross-Goerz double anastigmat, the Homocentric, the Teleros and the Xpres. In 1891, T. R. Dallmeyer had taken out the original patent for a telephoto lens, and in 1899 the Adon lens was introduced. In 1919 they introduced the Dallon, and in 1920 the Pentac.

The firm of R. & J. Beck had produced an iris diaphragm for photographic lenses in 1882 and were actively engaged in photographic lens manufacture from then onwards. Beck

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

also introduced the idea of using magnifiers in front of the lens with their Frena camera in 1894.

The biggest single English contribution to lens manufacture was undoubtedly the introduction by W. H. Dennis Taylor of the Cooke lens under patents taken out in 1893, 1895 and 1898 while working for Cooke of York. It was made and marketed by Taylor, Taylor & Hobson.

Cameras. In 1851 Richard Willats exhibited a portable collapsible camera at the Great Exhibition. It took pictures 8½ × 10½ ins. and collapsed to a depth of 4 ins. Up to 1875 there was little enlarging, so plate sizes were large. Pockets must have been larger too, because in 1855 the *Photographic Journal* carried an advertisement for a pocket camera taking a plate 5½ × 7 ins. and weighing 2 pounds 6 ounces.

Kinnear of Edinburgh introduced the bellows in 1857 and "Kinnear pattern" became a popular description.

Thomas Sutton introduced the first single lens reflex in 1861 and box cameras containing magazines of plates were advertised in England from 1880 onwards.

Melhuish and Spencer took out a patent for the first roll holder in 1854 and in 1888 Morgan and Kidds' roller slide in its largest form took twenty-four exposures 12 × 15 ins. and weighed 5 pounds 12 ounces.

The Frena camera of R. & J. Beck (1892) took up to forty cut films and in the last years of the century we had the various detective cameras including the Walking Stick and the Demon.

With the popularization of the celluloid roll film, development of simple cameras went rapidly ahead, Blair's "folding Kamaret" having been probably the first of the folding cameras which have been such a marked feature of the present century.

In recent years Britain has been noted mainly for the production of the simpler types of camera, in which it has a very large export trade, and for specialized types for the motion picture industry, for the services and for survey work.

British lenses have always been held in high repute, but there is still no large-scale manufacture of better quality shutters in this country. In this connexion it is worth recording that the focal plane shutter was invented by William England in 1861 and reintroduced by B. J. Edwards in 1879.

Industry and Research. In 1873 Chapman of Manchester and Burgess of Peckham started small-scale production of gelatin dry plates. By 1876 plates for the trade were being produced by the Liverpool Dry Plate Company and they were followed a few years later by Wratten & Wainwright and the Britannia Works Company, a private business founded by A. H. Harman who began to make plates in Ilford in 1879. In 1898 a public company was floated, known as the Britannia Works Company (1898) Limited, to take over the Harman enterprise and in 1900 the name of this company became Ilford Limited. It is interesting to note that in 1903 a proposal for the amalgamation of this company with Kodak was put forward and only narrowly defeated. The objectors held that it was important to maintain a native photographic manufacturing industry with control residing in the country and the plan was dropped. In 1912 Eastman absorbed Wratten & Wainwright. The work of Sir Ivor Philipps brought the amalgamation of many of the smaller manufacturing companies with Ilford to completion in 1930.

In the last thirty years Britain has changed from being the biggest importer of photographic materials to being one of the greatest exporters in the world. This success has been due first to continuity of effort. In Britain today there are companies with family names which were associated with the industry at the beginning. The name of Houghton goes back to 1834 when Mr. George Houghton entered into partnership with Antoine Claudet to sell glass in High Holborn. Claudet knew Daguerre, and Houghton and Claudet became for two years the sole licensees for the daguerreotype.

Secondly, the industry has had to face intense competition from abroad and that is stimulating. Thirdly, it has put an enormous amount of effort into photographic research and plant development.

In England, we tend to favour the amateur approach in scientific investigation, as in sport. Certainly in photography many important advances were made by men for whom photography was a pursuit of leisure hours. Fox Talbot himself was led to make his experiments because he wanted to draw and had no skill in draughtsmanship. Maddox was a doctor and J. B. Reade a minister. Sir John Herschel was a man of outstanding scientific ability with a flair for investigational work. Hurter and Driffield were technical men who interested themselves in photography as a hobby. Sir W. Abney was an instructor in chemistry to the Royal Engineers at Chatham.

In the manufacturing companies, research was at first very much an *ad hoc* affair and ingredients were added to emulsions simply to see what would happen. But when men like Sheppard, Mees and Renwick came along the position began to change. S. E. Sheppard and C. E. K. Mees were students at University College in 1900 under Sir William Ramsay, who suggested that they should repeat the work of Hurter and Driffield using improved apparatus. In 1903 the work gained for them the degree of B.Sc. by research. In 1903 they published joint papers on the theory of development in which the concept of gamma infinity first appeared. This collaboration went on until 1906 when Sheppard was awarded an 1851 Exhibi-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

tion Scholarship and went to Manchester to work with Karl Schaum on sensitizing dyes. The association was resumed in 1913 when he rejoined Mees in the new Eastman Research Laboratory at Rochester, U.S.A., where he worked at first on gelatin. Later he turned his attention to the structure and properties of silver halide emulsions in gelatin and went on to demonstrate that minute amounts of a labile sulphur compound in gelatin are responsible for its sensitising properties.

Mees, who had joined Wratten and Wainwright of Croydon in 1906, was invited by Eastman in 1912 to go to Rochester to direct the new laboratory. To enable him to go, Eastman acquired the Wratten and Wainwright concern and the subsequent story of his career is the story of the Eastman Kodak Research Laboratory. In 1913 he was joined by Capstaff, another research man of English birth.

Frank Forster Renwick was active in the affairs of the Royal Photographic Society, being President (1927–9), and very largely responsible for the emergence of the Scientific and Technical Group in 1919 and for the birth of the Photographic Alliance. He was particularly interested in the work of the British Photographic Research Association, formed after the first World War and sponsored by the manufacturers and the Department of Scientific and Industrial Research to promote the idea of co-operative research into fundamental problems.

This Association did much useful work but came to an end after the amalgamation of a number of British companies to form the Ilford group. The Research Association Staff were largely absorbed into this group.

Renwick was deeply interested in the work of Hurter and Driffield and made many contributions to the problem of tone reproduction. An early piece of work was the development with Ferguson and Benson of a special photometer for the measurement of photographic densities. He collaborated with Sir William Pope at Cambridge on sensitizers during the first World War. In 1922 he went to America, but by 1925 he was back with his old company, where he began building up the Ilford Laboratories with B. V. Storr and Olaf Bloch.

The Kodak Laboratories at Harrow, backed by the resources of the Eastman organization, also played a worthy part on this side of the Atlantic in the great advance in fundamental knowledge and in its practical application to new products. In Britain especially the photographic process has played a great part in nuclear physics since this science was born in 1896, when it was observed that radiation from a uranium salt fogged a photographic plate. Photography was used by Rutherford for much of his classical research on the alpha particle, and by Moseley in 1913 for his work which established the concept of the atomic number.

For Aston's research on isotopes Ilford Limited produced special plates in which the silver halide crystals protrude from the gelatin medium. These are still employed to record radiation which has minimal power to penetrate matter.

British scientists and manufacturers have led the world in the applications of special photographic emulsions to research on fundamental nuclear particles. For his work on special emulsions Dr. Waller of Ilford Limited has received the Duddell medal of the Physical Society and the Longstreth medal of the Franklin Institute of Pennsylvania. Professor C. F. Powell of the University of Bristol received the Nobel Prize for the discovery of the π-meson in cosmic radiation using photographic emulsions exposed on mountains. Balloon flights carrying emulsion more than 20 miles above the earth resulted in the discovery of many other transitory particles produced in atomic collisions at great energies, and this work has been extended to research with the machines that produce particles with energies up to 25,000 million electron volts.

Photographic Societies. An important factor in the development of photography in Britain is the interest in photographic clubs and societies, with the Royal Photographic Society at their head. Founded in 1853 at a meeting of the Royal Society of Arts as the Photographic Society of Great Britain, its first President was Sir Charles Locke Eastlake, who was also President of the Royal Academy and a painter of very considerable ability. Its founder and first secretary was Roger Fenton, famous for his pictures of the Crimea. In 1894, when Abney was President, it became the Royal Photographic Society of Great Britain, and ever since it has presented to the world a balanced conception of photography in all its aspects—aesthetic, scientific and learned.

There are about 1,000 photographic Societies in Great Britain, and these together comprise the Photographic Alliance.

Publications. The English photographic press has been another big influence. The senior member is The Royal Photographic Society's *Photographic Journal*, dating from 1853. Then follows *The British Journal of Photography*, the lineal descendant of *The Liverpool Photographic Journal*, first published in 1854 and edited by a committee of that society. Three years afterwards it was acquired by Henry Greenwood and became *The Liverpool and Manchester Journal*. In 1859 it became *The Photographic Journal* and it acquired its present title in 1860. The R.P.S. also publishes the *Journal of Photographic Abstracts*. Other contemporary photographic magazines in Britain include the following: *Photography*, *Photoguide Magazine*, *Amateur Photographer*, the Photographic Dealers' Association's *Photographic Retailer*, The Institute of British Photographers' *Record*, *Good Photography*, and the *Amateur Cine World*.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

Since the second World War, British books on photography have advanced into a leading position all over the world. They are read in larger numbers than books of any other origin and have been translated into more foreign languages than any other. British books have set patterns of approach to photographic subjects on almost every level which have stimulated foreign publishers far and wide.

British Photographers. The work of the early British photographers is still held in high regard the world over. The first of these pioneers was a Scot, David Octavius Hill, born at Perth in 1802. He studied painting at Edinburgh under Andrew Wilson. In 1843 he set out to portray on one canvas the 470 personages present at the General Assembly at which the Free Church of Scotland was founded, and at the suggestion of Sir David Brewster he made use of the calotype for his portrait studies. His portraits are still recognized as masterpieces, simple in treatment and straightforward in pose, full of quiet and noble dignity. It is widely believed that the technical control was in the hands of Robert Adamson of Burnside, Scotland, who was taught the calotype process by his brother, a colleague of Sir David Brewster, a friend of Fox Talbot.

The next was Roger Fenton, born in 1819, a founder and first secretary of what is now the Royal Photographic Society. He is mainly remembered for his work in photographing the Crimean War in 1855, some of his pictures being reproduced as wood engravings in the *Illustrated London News*. He was thus the first war photographer, although he was closely followed by others, notably Alexander Gardner of Paisley, Scotland, who went to America in 1856 with details of the wet plate process and became photographer to the army of the Potomac 1861–5.

The next landmark was the emergence of the composite picture which dominated the field for fourteen years. The development came about because of the impossibility with the collodion process of getting straight landscape negatives from which one could make prints with clouds showing in the skies. Then it came to be used as a means of making elaborate compositions with highly dramatic content. In England the phase began with the work of W. Lake Price and of O. G. Rejlander, a Swede living in this country. For one celebrated picture entitled *The Two Ways of Life* in the maner of a Renaissance painting, a composite picture 40 ins. in length which was exhibited at the Art Treasurer's Exhibition in Manchester in 1857, he used more than thirty negatives.

He was closely followed by Henry Peach Robinson, an artist who, like Fenton and Rejlander, had distinguished himself by having a painting hung in the Royal Academy. In 1858 he produced *Fading Away*, a composite picture made from five negatives portraying the death of a young girl. The technical quality of the picture was unchallenged, but its good taste was questioned and the controversy no doubt helped to make the name of the artist who became a dominating figure in photography and retained this position for over forty years. During this time he issued annually for subscribers a series of large prints made for the most part by combination printing, the publication of which is said to have marked the high point of the photographic year.

Mrs. Julia Margaret Cameron took up photography in the Isle of Wight in 1863, when she was 48. She knew many famous people and made them all sit for her. Her work is notable for the broad effects which gave character and greatness to her portraits.

With the coming of the dry plate the number of photographers greatly increased. Representative of this period is the work of Payne Jennings, B. Gay Wilkinson, J. B. B. Wellington and F. M. Sutcliffe.

In 1889 appeared a book, *Naturalistic Photography* by Dr. P. H. Emerson, which had a tremendous influence on the photographers of the day; it rejected handwork on prints and suggested that rules for composition were valueless.

The new approach to pictorialism was first apparent in the work of George Davison, whose picture *The Onion Field* has been described as the inspiration of the impressionist school of pictorial photography. Then came A. Horsley Hinton and Alexander Keighley who brought the technique of combination printing to perfection, perhaps with a little more artistry than was shown by some of their predecessors. Hinton's influence was enormous, not only because of his pictures but also because of his prolific writing on photographic matters. Over a period of thirty years Keighley exhibited hundreds of pictures of exceptionally high standard and in a romantic rather than a naturalistic vein. His early work was of the English scene, but he is remembered especially for pictures made in France and Italy.

With the formation in 1892 of the Linked Ring, pictorial photography in Great Britain arrived at its renaissance. Keighley, Horsley Hinton, H. P. Robinson and Davison were all concerned in its foundation, which came about because of the lack of encouragement which they found within the Photographic Society.

Around about this time too the work of Craig Annan began to be noticed. A townsman, he loved the country and had a strong sympathy for the Dutch school of painting. It was his practice to make straight negatives and to make his reproductions by photogravure. Also prominent at this time was Charles Job.

The next development concerned the introduction of the various printing processes involving control—e.g., gum-bichromate. Originating in France, these methods were taken up by Maskell, Mummery, Holcroft and Page Croft in this country. The platinum and gum

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

processes followed and the multiple gum prints of Batkin of Birmingham became notable features of exhibitions from 1903 to 1911.

In 1910 one of the most important events was the formation of the London Salon of Photography, in consequence of the decline of the "Linked Ring", which was first founded in 1892. The London Salon of Photography annual International Exhibition has continued without interruption ever since, and today it is universally recognized as one of the most important displays in the world, attracting thousands of entries every year.

Developments in America were closely followed in Britain. Stieglitz and Holland Day between them had a great deal to do with the founding of American pictorial photography and the work of both was well known in this country. Holland Day actually organized in London an exhibition of the new American School and on this occasion introduced his cousin, Alvin Langdon Coburn, who later worked and exhibited in Britain.

The period of the gum print came to an end about 1911 although some workers, notably Harold Leighton, continued to exhibit in this medium.

The oil and bromoil methods came next and in this period mention must be made of the names of Bertram Cox, J. H. Gear and F. J. Mortimer, whose seascapes are still unsurpassed. Like Hinton, Mortimer's influence went beyond his pictures. He was Secretary of the London Salon, editor of *Photograms* (suspended in 1962) and of the *Amateur Photographer*. He was killed in the second World War. J.Mi.

Industry. The United Kingdom photographic industry has shown a gradual overall expansion in recent years, both in terms of numbers employed and the value of output, although the number of manufacturing establishments has followed a declining trend. This has been due almost entirely to a reduction among firms and their employees producing apparatus, whilst sensitized goods manufacturers have remained almost constant in number and increased their workpeople during the period.

The most recent figures available are those of the 1958 Census of Production, which recorded 47 photographic manufacturing establishments with more than 25 employees each, together providing employment for 15,718 workpeople in that year. These were divided into 19 establishments with 3,356 employees producing photographic equipment, and 28 establishments employing 12,362 workpeople engaged in the manufacture of sensitized materials.

The industry is centred in the London area, where the two leading companies, Kodak and Ilford, are located and which together account for the major part of production and employment.

The larger organization, Kodak Ltd., is a subsidiary of the Eastman-Kodak Company of the United States, and undertakes the manufacture of all types of sensitized film, plates, paper and photographic chemicals, in addition to still and cine cameras, projectors and accessories, and photocopy equipment. It operates factories at Harrow, Middlesex (sensitized goods), Stevenage, Herts (equipment), Kirkby, Lancs. (chemicals) and a film processing plant at Hemel Hempstead, Herts., employing in 1963 a total of 10,700 persons.

Ilford Ltd., now partly owned by Imperial Chemical Industries, is a major producer of sensitized materials, in particular X-ray, black-and-white and colour film, in addition to marketing cameras and projectors made under its name by the West German firm of Dacora and the Japanese Elmo company. It also markets photocopy equipment. The company has its headquarters at Ilford, Essex (sensitized goods, especially plates), a film production plant at Brentwood, Essex, a factory at Mobberly, Cheshire (silver sensitized papers), and a plant at Basildon, Essex (chemicals and photocopy papers in addition to the processing of film).

The total number of persons employed in 1963 was 4,500.

The third largest photographic company is Johnsons of Hendon, Ltd., manufacturers of chemicals, dark room equipment and accessories, and importing agents for several leading makes of cameras and projectors.

Among other manufacturers of photographic goods in the U.K. are Coronet Ltd. at Birmingham, producing the cheaper range of still cameras, Specto Ltd. at Windsor, Berks., active in the field of still and cine projectors, Gnome Ltd. at Cardiff, Wales, well known for enlarging and projection equipment, and Wray Optical Ltd. at Bromley, Kent, manufacturing still projectors, enlargers and lenses. Important producers of 16 mm. and 35 mm. cine projection equipment are Rank Precision Industries and Associated Electrical Industries.

The British Photographic Manufacturers' Association is the official trade body representing the common interests of the industry.

It is supported by the majority of producers and derives its funds from their annual subscriptions.

Production. The value of photographic goods production has increased by slightly more than one-quarter over the five years from 1959 to reach a total of £57·2 million in 1963. Of this, about 15 per cent was accounted for by equipment, among which still cameras formed an important product with 1,240,000 units worth £2·1 million during the year, the majority of which were box-type models.

Output of both cine cameras and projectors has recorded a fall in value since 1959 to respective totals of £0·5 million and £2·0 million in 1963, the larger part in each case being attributable to 16 mm. and smaller gauge equipment.

The remaining four-fifths of the total value of production is due to sensitized materials, which

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

have shown substantial growth during the past five years to a total of £47·9 million in 1963.

The principal item is formed by the group comprising still film and plates, which includes X-ray film, and this has risen by 45 per cent in value in the period to £23·6 million in 1963. Sensitized paper and cloth together with cine film hold the shares of other sensitized goods produced, the former being worth £14·5 million and the latter £9·8 million during 1963, although the output value of paper and cloth has grown more rapidly since 1959 than that of cine film.

Imports. The value of apparatus and sensitized materials imported by the United Kingdom has shown an impressive increase during the past five years. In 1963, just over two-thirds of the £20·1 million total was composed of apparatus, among which still cameras formed an important item. Imports of these reached 937,000 units with a value of £3·6 million, of which 333,000 cameras worth £2·5 million were classified as 35 mm. or smaller format types.

The principal sources of still cameras in 1963 were West Germany, with 145,000 units valued at £1·2 million and Japan with 96,000 units worth £879,000; whilst Hong Kong supplied 564,000 cameras with a value of £328,000, the majority of which were box-type models.

Imports of cine cameras have followed a sharply rising trend since 1959 reaching 151,000 units worth £2·6 million in 1963. Nearly all of these are accounted for by 8 and 16 mm. models, supplied chiefly by Japan which has now gained the leading position among the sources with 66,600 units valued at £693,800, whilst West Germany was responsible for 18,300 cameras worth £327,000. Major items among imports of other equipment are still and cine projection apparatus, which together totalled 221,400 units with a value of £3·3 million during the year.

The value of sensitized materials imported is fairly evenly divided among the various types of product. The largest single item in 1963 was photographic paper and cloth, totalling £2·6 million, of which two-thirds in value was supplied by Belgium. Imports of cine film are

also of importance, reaching 168·7 million linear feet worth £1·6 million in 1963, among which 35 mm. stock accounted for 127·1 million linear feet with a value of £0·9 million, supplied chiefly by Belgium (73·3 million linear feet worth £0·4 million) and the U.S.A. (33·1 million linear feet worth £0·4 million).

Exports. The composition of exports of photographic goods reflects the pattern of production, with sensitized materials accounting for about a half of the £29·5 million total in 1963.

Apparatus exported has trebled in value during the past five years, among which cine cameras and cine projectors hold a leading place, the former reaching 6,600 units with a value of £1·1 million and the latter totalling 27,300 projectors worth £575,000 in 1963. The principal destinations of cine cameras were Italy (2,350 units valued at £110,000) and France (450 units worth £188,000). Among cine projectors, 16 mm. and smaller gauge models totalled 9,650 units worth £498,000, of which Australia received 1,500 projectors valued at £85,600 and Italy took 780 units with a value of £25,000.

Exports of still cameras in the same year

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

reached 132,300 units with a value of £999,000 the box type accounting for 117,400 units worth £124,000. Markets for the latter were widely spread, among the most important being France (12,200 cameras worth £12,500) and the Irish Republic (12,400 units valued at £11,600).

The value of sensitized materials has expanded by over one-third since 1959 to a total of £14·7 million in 1963. The most important single item, X-ray film, reached 35·8 million square feet worth £3·8 million, the principal markets being the U.S.A. and Canada, whilst the E.F.T.A. countries were also large customers.

Cine film represents the other most important product exported, with a total of 297·6 million linear feet valued at £3·5 million in 1963, approximately half of which in both quantity and value is accounted for by 35 mm. stock. Major purchasers of this are to be found among the E.F.T.A. countries, in particular Denmark and Sweden, whilst West Germany also receives a considerable amount. G.R.H. & A.G.B.

BRITISH BOARD OF FILM CENSORS. Statutory powers of film censorship in Great Britain are vested in the local authorities, who normally rely on the British Board of Film Censors to supervise the character of the films exhibited. The Board is an independent body, set up in 1912 on the initiative of the cinema industry. It views all films intended for public exhibition except newsreels. Three certificates are issued to approved films: "U"—"suitable for general exhibition"; "A"—"more suitable for exhibition to adult audiences"; "X"—"suitable for adults only". Children under 16 are not admitted to "A" films unless accompanied by an adult. They are excluded from performances of "X" films.

BRITISH FILM INSTITUTE. The British Film Institute was founded in 1933. It is governed by a board whose members are appointed by the Chancellor of the Exchequer, and part of its revenue is derived from a government grant; its function, as defined by the Redcliffe Committee in 1948, is "to encourage the development of the art of the film, to promote its use as a record of contemporary life and manners, and to foster public appreciation and study of it from those points of view." This purpose has recently been extended to include television.

One of the Institute's most important functions is to maintain the National Film Archive, in which are preserved films selected from current production for their special artistic, historical, social or scientific importance. The National Film Archive ranks as one of the major collections in the world and the films preserved under scientifically-controlled conditions (at Aston Clinton, Buckinghamshire) are valued at over a million pounds. Copies of some Archive films are available for hire from the Institute's own film library, which specializes in films on art and film classics, especially those of the silent era.

The National Film Theatre, opened in 1952, provides an admirable exhibition space for this and other material. It was constructed as the Telekinema for the Festival of Britain, 1951, and is specially equipped to show silent films at their proper speeds, as well as large-screen television and stereoscopic films. Its programmes present a steady repertory of acknowledged film masterpieces, as well as series devoted to the work of outstanding actors and directors, or to significant trends in the cinema. Every October the London Film Festival shows the best films of the year from all over the world. Associate membership of the Institute carries the right to receive the illustrated theatre programme and buy tickets.

With the object of raising the standards of the intelligent filmgoer, the Institute organizes conferences and publishes pamphlets, and each year has university extension courses in London and a Summer School in the country. It runs a lecture agency, arranging about 1,000 lectures a year.

The Institute has also pioneered in introducing film appreciation and practical film-making into school curricula, and given support to the Film Society Movement.

For full members, the Institute provides a library of books on film and television with loan and reference sections and an information and research service. Copies of rare stills may be bought from the stills library, the second largest collection in the world. Full members receive the Institute's quarterly film journal *Sight and Sound*, and concessionary rates for *The Monthly Film Bulletin*, containing reviews of all feature films, and for *Contrast*, a quarterly television journal.

The Institute has currently approximately 23,000 associate members and 10,000 full members. The headquarters and offices are in London.

BRITISH KINEMATOGRAPH SOCIETY. The British Kinematograph Society was founded in 1931 to encourage and further the scientific and technical aspects of kinematography and its allied arts and sciences.

There are five grades of membership, namely, fellows, corporate members, associate members, associates and students.

Membership is open to those gainfully occupied in the kinematograph industry or an allied or contributory industry, to those who, with the intention of entering the industry, are undergoing an approved course or serving under an approved apprenticeship scheme, and to those

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

who, although not gainfully occupied in the industry, can establish the satisfactory use of kinematographic processes for professional, scientific, educational or artistic purposes.

Within the Society four Divisions operate, representing the theatre, film production, industrial and specialized films and television. Each Division has an elected committee.

This organization affords means through its various channels for disseminating information on film production and exhibition, including television production as related to film and large screen reproduction.

The Society has representatives in India, Italy (both Rome and Milan), Denmark, South Africa, Australia, Holland, Sweden, Argentina, Japan and Brazil, and through these agencies promotes the interchange of technical information. The Society works in close liaison with kindred societies in the U.S.A.

The affairs of the Society are administered by a Council of which a proportion is elected annually. Five Officers, of which the President is chief, are vested with executive powers. In addition to the Divisional Committees. Theatre, Film Production, Industrial and Specialized Films and Television, business committees are appointed annually to be responsible for the work connected with Publications, Education, International Relations, Papers, Fellowship, Membership and Branches.

The Society and its Divisions hold monthly meetings in the winter season and organize part-time courses for laboratory technicians and theatre engineers. *British Kinematography*, the Society's journal, is published monthly.

BRITISH PHOTOGRAPHIC MANUFACTURERS ASSOCIATION. National association of manufacturers of photographic apparatus and materials which was incorporated in 1916 as a company limited by guarantee and not having a share capital.

The primary objects of the association are to organize, promote and protect the rights and interests of members of the association and to foster the development of the British photographic trade generally; it also facilitates the interchange by members of the association of their views on matters of common interest and promotes the consideration and discussion of all questions affecting the industry.

The association is regarded as the representative organization for British photographic manufacturers. It maintains close contact with government departments and is consulted on matters of general interest to the industry.

Contact is also maintained with kindred trade associations with a view to consultation and joint action wherever it is in their common interest.

The affairs of the association are conducted by a council, the members of which serve in an honorary capacity and are elected annually by the general body of members.

BROKEN NEGATIVE. If the glass of a negative is cracked but the emulsion film is undamaged, the trouble can be remedied by transferring the emulsion to another support.

See also: *Faults; Stripping.*

BROLOID PROCESS. One of the many variants of the basic carbro technique for building up a pigment image on a bromide print.

BROMETCHING. One method of preparing a bromide print so that the image assumes the texture of the support and looks something like an etching. The process involves over-exposing and then over-developing the print.

After washing, the print is exposed to the action of the etching solution (equal parts of 25 per cent sodium chloride solution, 5 per cent potassium permanganate solution and 4 per cent sulphuric acid solution in 20 to 30 times the volume of water). Fresh batches of solution are applied until the highlights are clear, and the print is then washed well, fixed in fresh acid fixer and then given a final wash. The result is a bold image with partcularly strong, pure blacks.

See also: *Sketch photograph.*

BROMIDE. Salt of hydrobromic acid. The principal bromides used in photography are silver bromide, ammonium bromide, potassium bromide.

BROMIDE PAPER. Most popular type of development paper for enlarging. The sensitive salt with which the paper is coated is silver bromide usually with a small silver iodide content. Invented and first produced in 1873 by Peter Mawdsley.

See also: *Papers.*

BROMIDE PENCIL. Special pencils once much used for working on bromide prints. They are made of crayon instead of graphite so that they will leave a matt finish to the work. The print must be either steamed or sprayed with artist's fixatif after applying the pencil to prevent it from rubbing off. They are manufactured in blue-black and brown-black tones. Nowadays most workers find retouching dyes easier to use.

See also: *Retouching.*

BROMOIL PROCESS. The bromoil process has largely replaced the former oil-pigment process because it can be applied equally to contact prints or enlargements. The print is made on the type of paper sold for bromoil work. It is then bleached—an operation which removes the black silver image but leaves it in a condition in which it will take up oil pig-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

BROMOIL PROCEDURE. 1. Bleach bromide print (should be made on paper without supercoating). 2. Wash until all stain is discharged. 3. Fix in a plain fixing bath. 4. Wash thoroughly. 5. Place wet bleached print on a glass plate and blot off excess moisture with a damp cloth or cotton wool. 6. Ink up with special bromoil brush and suitable greasy ink.

ment applied with a brush. So the final image is formed by oil pigment of any colour the photographer chooses.

Bleaching the Print. Prints for bromoil must be thoroughly fixed and washed. They should be dried and soaked in tepid water between 75° F. and 80° F., from 20 to 40 minutes according to the instructions issued by the maker of the paper.

There are several bleaching solutions. The following is satisfactory:—

Stock solution A		
Copper chloride	1½ ounces	37·5 grams
Sodium chloride	12 ounces	300 grams
Hydrochloric acid	10 minims	0·5 c.cm.
Water	40 ounces	1,000 c.cm.
Stock solution B		
Potassium bichromate	265 grains	15 grams
Water	40 ounces	1,000 c.cm.

The print is immersed in a bath consisting of equal parts of A and B and 2 parts of water. The solution is kept at a temperature of 65° F. to 75° F. When bleaching is complete, the print is washed until the yellow bichromate stain disappears, and it is then fixed in a plain hypo fixing bath (1 ounce hypo to 20 ounces water). It should be washed for about 20 minutes. Pigmenting may follow at once or the print may be dried and put to one side for pigmenting later.

If the print has been dried, it must be soaked in water at a temperature of 75° F. for half an hour before pigmenting.

Pigmenting. The wet bleached print is laid on a sheet of plate glass or similar smooth surface and the surface moisture is gently blotted off.

The print is then "inked up" with one of the special greasy inks supplied for the process. The condition of the ink is important. If it is too hard it will not adhere to the print; if too soft it will adhere equally to highlights and shadows. Special thinning medium is available for bringing the ink to the required consistency.

The ink is applied with a special flat bristle bromoil brush held vertically and dabbed gently over the surface. The art of bromoil is in the brush action—sometimes called hopping—and it must be acquired before the worker can achieve real control of the tones of the finished picture.

The ideal method of working is for the gelatin to absorb the pigment gradually so that the image is gradually built up. Some parts of the print may be made darker than the original bromide and in others, action with a dry brush will remove the pigment and lighten the tone.

Bromoil Transfer. By an extension of the process an impression of the inked image can be transferred by pressure to another base. Bromoil transfer, as it is termed, needs expert manipulation and a specially constructed press. The results have a delicate and recognizable character of their own.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The bromoil print is made as before described. Success will depend upon the choice of suitable inks and the paper upon which the work is done. The special papers made for the bromoil process should be used.

Generally a hard ink will transfer more easily and without the risk of spoiling the outlines of the image. The print for transfer should be vigorous, and strongly inked if it is to transfer without loss of quality. Any control necessary is best done on the bromoil print before transfer.

For transfer a specially designed press is used. The selected paper must have a slightly rough surface and be uncoated. The press generally consists of pressure rollers. It is important that the pressure be even and regular. If it is too heavy, the transfer is unsharp; if too light the transfer will not take place. The old type office letter press has been used, as well as the roller type domestic ringer, but it will be necessary to experiment with such improvised equipment before attempting serious work.

The transfer must take place while the print is still moist, but not too wet. The bromoil print and the paper, which should be larger than the print, are laid in contact. It is best to lower the transfer paper on to the print from one side as this avoids air being trapped between the two. Care must be taken not to move the two once they are together as the result would be a blurred image.

The two papers are then passed through the press. The bromoil is gently pulled away from the transfer paper and if all has gone well the image will have been transferred.

The image will be reversed left for right after the transfer. If this is a disadvantage it may be corrected by making the exposure through the back of the negative. This is quite easy when enlarging and should always be done when a transfer may be required. R.M.F.

See also: *Control processes; Pigment processes.*
Book: *Bromoil and Transfer*, by C. J. Symes (London).

BROOM, CHRISTINA, 1863–1939. English photographer, probably the first woman press photographer. Began free-lance work at the age of forty and published her photographs as postcards and sometimes also in newspapers. Photographed suffragette and other political meetings and royal occasions.

BROWN, GEORGE EDWARD, 1872–1934. English chemist, writer and journalist. Editor of *The British Journal of Photography* and the *B.J. Almanac* from 1906–34.

BROWNIE. Trade name of the first of the simple, mass-produced box cameras—often indiscriminately applied in describing any make of simple camera. It was first manufactured by Kodak in 1900 and helped spread of snapshot photography among the general public.

BRUGUIÈRE, FRANCIS, 1880–1945. American photographer born in France. Started photographic career in San Francisco, of which he published a book of his photographs in 1918. Believing that current practice of imitating painting in photography was futile, he photographed abstract constructions, using the camera to record light effects on them. In 1927, he held an exhibition of his abstract photographs at The Art Centre in New York, followed by exhibitions in London and Berlin. In 1937, produced the photo-murals for the British Pavilion at the Paris Exhibition.

BRUSH DEVELOPMENT. Development carried out by swabbing the solution on to the exposed material with a brush or mop—usually applied to prints too large to fit the available dishes.

BRUSHES. The most suitable brushes for colouring, retouching and spotting are of the type used by artists.

Apart from artist's brushes, photographers occasionally need convenient tools for spreading and coating solutions on to various supports.

Retouching Brushes. The best brushes for spotting and touching out small blemishes are those manufactured for miniature painting. These are known as "red sable" brushes and are available in a range of sizes. The lower the

BRUSH TYPES. Top: *Retouching brushes. Usually these are very fine, but a thick brush can easily come to a point, too.* Centre: *Blanchard brush, consisting of a piece of fluffless material tied over the end of a piece of glass or plastic.* Bottom: *Buckle brush made by pulling a ball of cotton wool into the end of a glass tube. A loop of wire holds the cotton wool.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

number stamped on the shank, the finer the brush. For spotting negatives a No. 00 is satisfactory while the slightly larger No. 0 is best for enlargements. For painting out small areas and outlining on the negative before blocking out, a No. 1 water colour sable is the right size, while laying broad washes calls for a No. 3, 4 or 5.

When the point of a brush is marred by projecting hairs, the brush should be moistened, drawn to a point, and then lightly passed over the flame of a match. It is worth noting that the smallest brush does not necessarily give the finest point.

Colour Brushes. Good quality artist's water colour brushes are the best for colouring prints and slides. The No. 1 size is suitable for colouring details, No. 3 for normal work on the print and for really broad washes, a No. 5 or larger will save time and give a more even result. Where a number of colours are being used on the same print, it is more economical to buy a set of quills, one for each colour, and use them as required on the end of a common shank.

The tip of a good quality brush should spring straight again immediately after being bent by pressure on a flat surface.

Blanchard Brush. The name for a spreader used for coating surfaces with a fluid medium, e.g., for applying the sensitizer to the paper base in the gum bichromate process.

The brush is made by folding a piece of fluffless material over the end of a piece of glass or plastic about 2 ins. wide and securing it with a rubber band. Once used, the material is discarded and replaced by a fresh piece when the brush is used again.

Buckle Brush. This brush is made from a short length of glass tube, preferably shaped to a bell-mouth at one end. A loop of string is passed down the tube and a piece of cotton wool or sponge is caught in the loop. By tightening the string, the material is wedged into the end of the tube and can be used for various brushing or swabbing operations.

Here again, when the material forming the head of the brush has served its purpose, it can be replaced by a clean piece.

B.S. SPEED. System of rating the speed of sensitized materials, laid down by the British Standards Institution in the British Standard No. 1380: Part 1: 1962 for black-and-white negative materials and in No. 1380: Part 2: 1963 for colour reversal materials. The B.S. speed is based on measurement of a prescribed point or points on the characteristic curve, the specifications for which are identical with the conditions laid down in corresponding A.S.A. (American) Standards.

The B.S. speed is expressed either as an arithmetical speed—e.g., B.S. 100—or in a logarithmic form to a base 2—e.g. B.S. 5°. This logarithmic form is frequently quoted in conjunction with the arithmetic form—e.g. B.S. 100/5°.

These notations are identical with the A.S.A. system, and are based on the same criterion as the speeds specified in the German Standard DIN 4512 of 1961. The B.S. Standard No. 1380: 1962 however also retains as obsolescent a logarithm base 10 speed scale, where every doubling of the speed corresponds to an increase of 3° in the logarithmic figure. Hence B.S. 100 is equivalent to B.S. Log 31°. This latter figure is never quoted in conjunction with the arithmetic speed (unlike the log base 2 speed), and is intended to be discontinued eventually. Its transitional retention is based on the fairly widespread use of logarithm base 10 speed figures in Britain before the publication of B.S. 1380: Part 1: 1962.

See also: *A.S.A. speed; Speed of sensitized materials.*

BUBBLE CHAMBER PHOTOGRAPHY. Technique of photographing nuclear particles by means of the bubbles they release in a super-heated liquid. Has in recent years become a specialized tool in nuclear research, quite distinct from the recording of tracks in nuclear emulsions, and the photography of the events in cloud chambers, although the latter problem is very similar to that of bubble chamber photography.

Basically a bubble chamber is a means of studying the interaction of charged particles (e.g., protons, electrons and other elementary parts of matter) with the atomic nuclei of the medium in the chamber. The particles are released into the chamber with extremely high energy, usually after acceleration by an electrostatic field in a proton-synchrotron. The particles can enter the bubble chamber directly, or can be made to strike a thin metal target, so producing particles other than protons. As an example of the energy levels attained, the proton-synchrotron at C.E.R.N., Geneva, supplies energies of 30 GeV, and the particles are travelling at speeds so close to that of light that the relativistic mass increase is about 30 times.

Types of Bubble Chamber. A bubble chamber operates on the principle that a charged particle passing through a super-heated liquid causes boiling to occur along its path. The analogous situation in a cloud chamber is that of an ionizing particle leaving a trail of droplets in a supercooled vapour. The advantage of a bubble chamber lies in the greater density of the medium, giving a much higher probability of a particle being stopped within the chamber, and ensuring a greater number of collisions with the atomic nuclei of the medium.

The most favoured liquids for use in a chamber are hydrogen, helium, or a simple hydrocarbon such as propane. Hydrogen is considered particularly useful because the nucleus is very simple, consisting of one proton only. Propane, however, is more easy to work

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

BUBBLE CHAMBER SET-UP. The light beam from the flash is projected through the bubble chamber to a point in between three cameras spaced 120 degrees apart. The cameras thus do not record the flash itself, but photographs any bubble tracks formed by nuclear particles. The bubbles scatter the light beam and so show up as bright against the dark background. The use of multiple cameras permits more accurate location in depth as well as separation of several tracks. A, glass windows of bubble chamber, usually about 50 cm. in diameter. B, flash source. C, condenser. D, beam aperture. E, image of flash between cameras. F, cameras.

with, and presents less severe optical problems although having a more complicated nucleus.

For photographing particle tracks in a hydrogen bubble chamber, a condenser behind the chamber focuses an image of an electronic flash close to the camera lenses. Usually at least three cameras are used to obtain at least two good views over the whole of the chamber. This provides dark-ground illumination with no direct light reaching the camera lenses. A bubble is visible on account of the small amount of light scattered sideways from the main beam. Hydrogen has a very low refractive index (about 1·09) so that at 10° from the main beam the scattered light has about ⅓ the intensity of that passing straight through the bubble, and at 20° it has dropped to 1/10. The image of the flash tube must therefore be very close to the camera lenses. Only the blue light from the flash is used (with a non-colour sensitized film), partly to eliminate partial light spill into the camera lens by the chromatic aberration of the condenser, and partly to obtain maximum image resolution.

Because the liquid in the chamber is under high pressure, the transparent faces of the chamber must be of very thick glass of high optical quality to avoid distortion of the bubble tracks. The glass faces are coated to reduce the reflectance in the part of the spectrum used. (The inner faces of the glass are not optically eliminated by being in contact with the liquid, as is usually the case, because of the very low refractive index of hydrogen.)

With propane, the light scattered out of the main beam is so much higher that the flash tubes can be placed at one side of the chamber, with the light refracted through approximately 90°. Thus no rear window or condenser system is required, and a wider band of the spectrum can be used for recording. However, these advantages in the optical system are considered by many workers not to outweigh the advantages of the simple nucleus of the hydrogen atom.

For operation of the chamber, the pressure of the liquid is normally kept above that of the vapour. Just before the entry of the particle beam, the pressure is reduced, and after a delay of about 5 milliseconds, depending on the exact conditions and the availability of light, a flash exposure of about 100 to 200 microseconds duration is made of the bubbles, and the pressure immediately restored.

Photographic Problems. Bubble chamber photography needs a fast enough film, as the camera lenses are stopped down to *f*16 or even *f*32 for adequate depth of field through the chamber. With a bubble size of less than 0·5 mm. and a 15 times reduction, the film records merely the light points due to the bubbles. After formation the bubbles begin to grow, which to the camera lenses appears as an increase in brightness. With a fast film the bubbles can be photographed immediately, before currents in the liquid distort the tracks, or the liquid as a whole begins to boil.

THE BUBBLE CHAMBER OPERATIONAL CYCLE. At the beginning of the cycle the liquid pressure (solid line) is lowered and then the beam allowed to pass through (A). The flash is fired and the photograph taken at point B, after which the liquid pressure is restored while the film is advanced and the system got ready for the next cycle. The dotted line indicates the vapour pressure; when the liquid pressure drops below this level the bubbles are formed when any ionizing particles pass through the chamber.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

This film speed must be consistent with adequate resolution. The central part of the diffraction pattern of an optical system working at *f* 16 is about 15 μ, and that from an *f* 32 system is about 30 μ. The resolution of the film need not therefore be infinitely high in view of this low optical resolution. On the other hand the images of the bubbles must not be appreciably enlarged by light scatter in the emulsion or the individual images will be joined.

The recording of an interesting track or collection of tracks is partly a matter of luck. It is customary to take many thousands of pictures, select the ones suitable for detailed examination and put them in a tracking machine which follows along a track with a photoelectric scanner, recording the co-ordinates on punched tape, ready for insertion into a computer. The film must therefore have many of the properties normally associated with ciné film: freedom from static discharge when wound on rapidly, stability in storage both before exposure and between exposure and development, and tolerance to rapid processing—possibly at a high temperature. The positions of individual bubbles may have to be measured with an accuracy of about ± 2 μ; this is not possible over several inches of film owing to the unpredictable distortions in the base. However, by placing fiducial marks on the glass windows of the chamber so that reference points appear every centimetre or so on the film, this accuracy can be achieved on ordinary commercial films using triacetate base. The tracks must also be of sufficient density to be detected by the tracking machines. If the image is to be closely confined to the region of the original optical image, this calls for a film with as high a contrast as possible, consistent with accepting a wide enough range of exposures. Further, the granularity of the developed image must be sufficiently low to avoid errors in interpreting the positions of bubbles.

Usually the most satisfactory compromise between the various requirements of the sensitive material is a film of 40–160 ASA, developed to a considerably higher contrast than that used in normal camera work. Sometimes a faster film with coarser grain can be used if the emphasis is on the positions of tracks rather than of individual bubbles. M.G.F.

BUBBLES IN LENSES. Small bubbles sometimes seen in the glass of a lens but which do not normally affect its performance. On some lenses, the bubbles are touched over with blacking to minimize any light scatter.

See also: *Optical glass; Second-hand equipment.*

BUCKLE BRUSH. Swab holder for applying liquids, consisting of a ball of cotton wool wedged in the end of a tube. Invented *c.* 1855 by Samuel Buckle, for coating calotype paper.

See also: *Brushes.*

BUFFER. Alkaline salt of a weak acid which tends to maintain the necessary alkalinity of a developer in the presence of acids liberated by the action of the developer. Some typical examples are sodium carbonate, sodium metaborate and sodium phosphate.

See also: *Alkali; pH value.*

BULB EXPOSURE (B). Another term for a brief exposure—in which the shutter remains open only so long as the shutter release is held down. The word originated with the early pneumatic shutter release.

BULB FITTING. Connector cap, forming part of electric lamp, secures the lamp in the holder and connects it to the electricity supply. The shape and size of the fitting varies with the type of lamp.

See also: *Lamp caps and fittings.*

BUNSEN, ROBERT, 1811–99. German Professor of Chemistry at Heidelberg University. In collaboration with the English chemist, Henry (later Sir Henry) E. Roscoe, he discovered the Bunsen-Roscoe Law, sometimes called the law of photochemical reciprocity. With R. Kirchhoff, Bunsen laid the foundations of spectrum analysis in 1860. Bunsen invented the "grease spot" photometer and introduced magnesium (ribbon) light (1859).

BURGESS, JOHN. Dates unknown. English photographer. Improved Maddox's silver bromide gelatin process and started small-scale commercial production of dry plates in 1873. From 1880 also manufactured silver bromide paper.

BURNING-IN. Local extra exposure to a print, to darken selected picture areas which will otherwise show the image lighter than desired. When this is carried out by additional exposure to the image, detail becomes stronger. Burning-in can also be done with a fogging light (for example a thin pencil-like torch beam) and this darkens the print locally and also obliterates detail.

See also: *Shading and spot printing.*

BUSCH, EMIL, 1820–88. German optical manufacturer. Founded optical works in Rathenow which produced in 1857 the famous 6 ins. and 7 ins. diameter lenses for cameras and in 1866 a 10 ins. diameter lens giving pictures 30 × 30 ins. with a focal length of 34 ins. Busch also designed well-known combination lenses for portraits and landscapes.

C

CABINET PHOTOGRAPH. The cabinet format, introduced by G. W. Wilson for views, 1862, became general only after its application to portraits by F. R. Window four years later. The picture usually measures 4 × 5½ ins. on a mount 4¼ × 6½ ins. It was largely superseded by the postcard size around 1900, and died out during World War I.

See also: *Sizes and packings.*

CABLE RELEASE. Camera accessory used for releasing the shutter without touching the camera itself. It consists of a stiff wire inside a flexible outer casing similar to that of a Bowden cable but smaller in diameter. The casing carries a threaded nipple at one end to screw into a suitable socket on the camera shutter. The other end has a plunger which, when depressed, releases the shutter.

A modified form of cable release has a locking screw or a spring-loaded catch that can be engaged with the plunger to hold it in the depressed position. This enables the release to be used for holding the shutter open for making long exposures with the shutter control set at B.

See also: *Shutter release.*

CADMIUM LAMP. Mercury vapour discharge lamp containing cadmium. This compensates for the complete absence of red in a mercury vapour discharge and thus produces a reasonably balanced spectral emission.

CADMIUM SULPHIDE. Semi-conductor which increases in conductivity of electric currents when exposed to light. The conductivity is proportional to the logarithm of the light intensity. Used in photo-resistor cells for exposure control and exposure measurement. Unlike a selenium cell, a cadmium sulphide cell requires an external source of current. Exposure meters incorporating cadmium sulphide cells therefore measure the current flowing through the cell.

See also: *Exposure meter; Photo-electric cell.*

CALGON. Proprietary name for sodium hexametaphosphate. It is used to soften hard water.

CALLIER, ANDRÉ, 1877–1938. Belgian amateur physicist. Did valuable work on sensitometry and densitometry for which he received the Progress Medal of the Royal Photographic Society in 1915. Discovered that diffuse density differs from specular density by a factor Q (the Callier coefficient).

CALLIER EFFECT. Selective scattering of light in an enlarger or similar optical system; first investigated by André Callier in 1909.

In an enlarger the condenser is normally adjusted so that the light leaving it comes to a focus at the lens when there is no negative in the carrier. With a negative in the carrier, part of this light is scattered by the silver grains forming the image. So this part does not reach the enlarging lens. The highlights of the negative, corresponding to the heaviest deposit of silver, scatter and lose most light; the clearer parts, corresponding to the shadows, scatter least. This accentuates the difference between the highlights and shadows and gives a print of higher contrast than if printed by contact.

CALLIER EFFECT. **Left:** *In a condenser enlarger the directional light is preferentially scattered by the negative densities, increasing effective image contrast.* **Right:** *In a diffuser enlarger all negative areas scatter equally.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Because of the Callier effect, the density of an even image area on a photographic negative or transparency is greater when measured by directed light (specular density) than when measured by diffused light (diffuse density). In the former case the density is due to absorption as well as scattering of light; in the latter case to absorption only. The ratio of specular to diffuse density is the Callier quotient or coefficient, and depends largely on the grain size of the image.

The effect is only noticeable when the light falling on each point of the negative is in the form of a bundle of more or less parallel rays, i.e., when a small light source and a condenser are used. When the light falling on the negative is already diffused the contrast of the negative is reproduced in the print without extra emphasis.

See also: *Density; Enlarger.*

CALOTYPE. (Talbotype). Process for making paper negatives in the camera. Not to be confused with collotype, which is a photomechanical reproduction process. Calotype was patented by Fox Talbot in 1841.

The basic process employed iodized paper—i.e., best quality letter paper brushed over with a solution of silver iodide and potassium iodide and allowed to dry. Before use the paper was treated with a solution consisting of silver nitrate, acetic acid and gallic acid crystals. The paper could then be exposed in the camera either wet or after drying, exposure being around five minutes at *f* 8 in bright sunlight. After exposure, development was carried out in a silver nitrate and gallic acid solution similar to that used for preparing the iodized paper for exposure. It was then rinsed, fixed in "hypo", washed and dried. The printing time of the resulting paper negative could be shortened by waxing the back of the paper to make it more translucent.

After the introduction of the collodion process the calotype process became obsolete.

CAMERA. (Latin camera = a room.) Device for making a record of the image of an object formed when rays of light pass through a lens and fall on a flat surface. The essential parts of a camera are a chamber into which light can only be admitted by a lens, when a shutter is opened, to form an image on a layer of light-sensitive material.

Basic Design. The simplest form of camera has no lens at all; light is admitted through a pinhole and forms an inverted image on the sensitized material. The brilliance of the image is very low, however, and a pinhole camera calls for unduly long exposures in consequence. A lens allows more light to pass and makes it possible to use short exposures.

CAMERA TYPES. The photographic camera evolved along a few basic lines, from which all current types are derived. Top: Box camera; the simplest form (available for amateur use from the end of the nineteenth century) with its modern streamlined counterpart. Upper centre: Studio camera with variable bellows extension; giving rise to present-day technical, field, and press models as well as the amateur folding roll-film camera. Lower centre: Reflex camera, and modern twin-lens reflex and miniature single lens reflex with eye-level finder. Bottom: 35 mm. cine camera, with the 35 mm. precision miniature developed from an experimental camera for testing cine film, and provided with most advanced features.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The light passing through the lens is controlled in intensity by an adjustable diaphragm. A shutter is used to regulate the duration of the exposure. The diaphragm may be located in front of the lens, between its components, or just behind it. The shutter may be fitted in any of these positions or it may work immediately in front of the sensitized material. The shutter allows the light falling on the lens to pass through on to the sensitized material for periods of time as brief as 1/1000 of a second or less or for as long as required.

Many modern cameras incorporate an exposure meter which indicates the required settings of lens and aperture or even adjusts them automatically to the prevailing light.

Most cameras are made to take sensitized materials in the form of either films or plates. The camera has provision for holding these materials so that they can easily be changed or removed.

The camera must also have some means for sighting so that the image of the subject to be photographed will fall in the required position on the sensitized material when the shutter opens. For this purpose nearly all cameras have some form of viewfinder. This may be either an optical sighting device, or a focusing screen fitted so that it receives the same image as the sensitized material.

The lens position is usually adjustable to enable the camera to record sharply objects at different distances. The actual distance setting may be carried out with the aid of a distance scale or with an optical focusing device (e.g. rangefinder) or by visual observation on a focusing screen.

Basic Types. Modern cameras, although following this elementary design, usually incorporate individual features which have led to the creation of basic types, as follows: the sub-miniature, extremely small in both construction and film size; the miniature, taking perforated 35 mm. film and usually employing a range of accessories; the folding camera, medium size, folding into a compact form when not in use; the box camera, cheap and simple in construction; the reflex camera, any size, but embodying a special viewfinder system through which correct focusing can be accurately determined; the technical camera, usually for larger formats, with a wide range of adjustments of the lens and image plane.

These different types may include further refinements which make the camera particularly suitable for specialized work—e.g., scientific research, photomechanical reproduction and even applications such as gunnery practice and underwater photography.

Modern precision cameras are also available with comprehensive accessories designed to adapt the camera for specialized uses; the miniature camera is the most notable example.

CAMERA GUIDES. Series of pocket books published by the Focal Press, each dealing with a well-established make of camera and its accessories. The pedigree, construction, method of use and scope of each camera is presented comprehensively, accurately and objectively, and new editions of each Guide are published to keep pace with improvements and new models.

CAMERA HISTORY

The invention of photography is generally ascribed to those experimenters who first succeeded in producing a permanent camera image. The development of the camera, however, started considerably earlier though its application to photography had to wait until chemical knowledge had advanced sufficiently.

The Camera Obscura. The photographic camera derives directly from the camera obscura. This was originally, as its name implies, literally a darkroom, with a tiny hole in the roof, wall, or window shutters through which the view outside was projected upside down on to the opposite wall, or a white screen placed opposite the hole. Its invention has been erroneously ascribed by various writers to Roger Bacon, Alberti, Leonardo da Vinci, and Giovanni Battista Porta. In fact it was described by the Arabian scholar Alhazen before 1039, i.e., about 250 years before Bacon. Since Alhazen's account does not in any way imply that he divulges a novel observation, it may be assumed that this knowledge was fairly widespread amongst Arab scholars.

In 1550, Gardano had fitted a bi-convex lens in the hole. In 1568 Daniel Barbaro recommended the addition of a diaphragm to sharpen the image, and in 1573 Danti suggested reflecting the images from a concave mirror to make them upright.

After Porta had in 1558 recommended the use of the camera obscura as an aid to artists, various forms were evolved, including tents, cubicles carried on poles, and even small portable and, later on, pocket models.

The portable reflex camera, with a mirror set at an angle of 45° to the lens, appears to be due to the mathematician Johann Sturm in

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

1676. A further reduction in size, replacement of the ordinary spectacle lens by a lens combination fitted in a brass tube, and substitution of a ground glass for the sheet of oiled paper, made the various camera types illustrated by Johann Zahn in 1685 the forerunners of nineteenth century box and reflex cameras.

The Photographic Camera. The evolution of the photographic camera in the nineteenth century —from the cumbersome apparatus needing a porter to the "detective" camera hidden in a walking-stick or a book—is in many ways analogous to that of the earlier drawing instrument.

Nicéphore Niépce was the first successfully to apply the camera obscura to photography (1826). One of his cameras incorporated an accordion-like square bellows and another variable iris diaphragms—prototypes of modern camera features. Also noteworthy is the fact that one of Niépce's instruments was made of zinc. In order to observe the progress of the image during the long exposure Niépce made a little spy-hole in the camera box, which he plugged up. The same device was later used by Fox Talbot.

The various lenses used by Niépce no longer exist, but from his letters it is known that W. H. Wollaston's periscopic lens (a meniscus prism) which he bought from Chevalier in 1828 gave better all-round sharpness than any previous lens he had used.

Daguerreotype Cameras. The camera which became generally known by Daguerre's name at the time the daguerreotype process was published in 1839 consisted of two boxes, the rear part with the ground-glass sliding within the front part containing the lens. Those which were made by Alphonse Giroux, a relative of Madame Daguerre's who for a few months had a monopoly in the manufacture of these cameras, bear Giroux's guarantee and seal and Daguerre's signature. They are 12¼ ins. high, 14½ ins. wide, 10½ ins. long when closed, extending to 20 ins., for use with metal plates 6½ × 8½ ins. and cost 400 francs (then £16). The camera was not patented however (except in England) and numerous similar and cheaper models were soon made by other firms all over the world. Daguerre's design remained the standard type for several decades, both for studio and fieldwork.

CHEVALIER'S COLLAPSIBLE WOODEN CAMERA. The body is hinged in the middle and folds up sideways after removal of lens panel and focusing screen.

DAGUERRE'S CAMERA. Made originally by Alphonse Giroux, the camera consisted of two boxes which slid inside each other for focusing the lens on the ground-glass screen at the back. A simple brass disc in front of the lens acted as a shutter. The plate size was 6½ × 8½ ins. (i.e., the original "whole plate"). The lens was a Wollaston type achromatic lens with a focal length of 15 ins., and an effective aperture of f 14.

Most of these Giroux cameras were fitted with a Wollaston type achromatic meniscus prism of 1829 by Chevalier. The lens had a focal length of 15 ins. and was contained in a brass mount with a simple brass disc acting as shutter. The effective aperture of the lens was reduced to *f* 14 by a 1⅛ ins. stop fixed inside the lens tube, which gave great sharpness to the image. Since Chevalier could not produce the lenses quickly enough to meet the demand, some of the Giroux cameras were fitted with lenses made by Lerebours and other Parisian opticians. These latter lenses are of the plano-convex type, with a focal length of 16 ins., and had an effective aperture of *f* 17.

Under these circumstances it is not surprising that for the first year or so exposures were 20 to 30 minutes in full sunshine. In order to reduce exposures to a reasonable length it was soon evident that smaller cameras, fitted with lenses of short focus and wide aperture, were called for. Landscape and architectural photographers, too, though less troubled by length of exposure, were eager to reduce the bulk of the apparatus, which in the daguerreotype process required, in addition to the camera, a plate box, iodizing box, mercury developing box, spirit lamp, and other paraphernalia, the total weight being 110 lbs.

Baron Séguier in December, 1839, introduced a cheaper and less bulky outfit in the form of a collapsible bellows camera. With the entire equipment, this could be packed inside a large box acting as carrying case. Séguier's outfit

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

weighed 35 continental pounds and took only one-third of the volume of Giroux's though taking pictures the same size. Séguier also introduced the photographic tripod (previous cameras were placed on some kind of solid stand or table), the ball-and-socket head and the darkroom tent.

Chevalier's "Photographe", introduced in 1840, was a wooden folding camera in which the long sides were made collapsible (after the lens-board and ground-glass had been removed) by being divided horizontally along the middle and hinged. The following year he supplied also half-plate and quarter-plate models of the usual rigid box type, fitted with a single (and later double) achromatic plano-convex lens.

Buron, another Parisian instrument maker, introduced a quarter-plate camera with two lenses, one of 20 cm. ($7\frac{7}{8}$ ins.) focal length for landscapes, and one of 8 cm. ($3\frac{1}{8}$ ins.) focal length for portraits. In conjunction with one-eighth plates this was claimed to require only one minute exposure in full sunshine. In practice, however, exposures were considerably longer and everyone objected to their grimaces, due to the direct sunshine, as being a far cry from the promised likeness of "the human face divine".

In the attempt to find a solution, Alexander S. Wolcott, a New York manufacturer of dental supplies, took out a U.S. patent for a mirror camera in May, 1840. This wooden box had instead of the lens a large open front through which the light passed on to a 7 ins. concave mirror inside; this reflected the light and formed an image on the sensitized plate, which was fixed in the centre of the open front facing the mirror. This had the advantage of accepting more light, and the image was not reversed. The 12 ins. focal length mirror, however, limited the size of the portrait to 2 sq. ins., and the image was slightly soft. Exposures indoors were at first 3 to 5 minutes, but, after chemical acceleration of the daguerreotype plate had been invented, they were reduced to 60–90 seconds. The mirror camera

WOLCOTT'S MIRROR CAMERA. *Patented in 1840, this camera had no lens, but instead formed the image by means of a large concave mirror at the rear. The image was reflected to the plate in front of the mirror. The plate holder was adjustable to allow for focusing the image. In the beginning this permitted exposures of 3–5 minutes (compared with an exposure of 20–30 minutes with Daguerre's camera).*

VOIGTLÄNDER'S ALL-METAL CAMERA. *This was introduced in 1841, and was fitted with a Petzval lens of effective aperture f 3·6, the fastest lens of its time. It took circular pictures $3\frac{1}{2}$ ins. in diameter, with exposures of around 1 minute.*

enabled Wolcott to open the world's first public portrait studio, in New York in March, 1840. Twelve months later, Richard Beard, who had acquired the exclusive rights for Wolcott's camera in Britain, opened in London the first public studio in Europe.

The general demand for a quick-acting portrait lens prompted the Viennese mathematician, Professor J. Petzval, to compute one for Voigtländer & Co., who designed a conical-shaped camera in conjunction with it. Both were introduced in January, 1841, and with them it was possible, even before methods of chemical acceleration had been devised, to take portraits in about a minute. The Voigtländer camera, which was made in two models, wood or brass, took circular pictures 9 cm. ($3\frac{1}{2}$ ins.) in diameter.

Petzval's double combination lens had a large aperture (*f* 3·6) and a fairly short focal length of 15 cm. (6 ins.) giving excellent definition in the picture centre without the use of a stop. It was thus thirty times faster than the Chevalier and Lerebours lenses in the Giroux cameras. The lens, which was also made in various other focal lengths for use in ordinary daguerreotype cameras, revolutionized portrait photography and remained the most generally used lens type all over the world until the introduction of Paul Rudolph's anastigmat by Zeiss in 1889. The Voigtländer and Wolcott cameras, on the other hand, were superseded as soon as the speeding up of the daguerreotype process by chemical methods had made the taking of larger portraits possible.

Cameras for the Calotype. Fox Talbot had his first cameras constructed in 1834 by a local carpenter. To arrive at exposures of reasonable length, they were made very small at first, measuring no more than $2\frac{1}{2} \times 2\frac{1}{2}$ ins., the picture area being 1 in. square. As they were fitted with a 2 ins. fixed-focus microscope lens,

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

PETZVAL STUDIO CAMERA. One interesting feature is the monorail construction like an optical bench, used again a century later in modern technical cameras.

the ground-glass could be dispensed with. To see how far the image had imprinted itself on the paper, Talbot had spy-holes made in the lens-board. His final camera design, like Niépce's and Daguerre's cameras, consisted of two boxes, the rear part sliding within the front box.

Richard Willatts of London exhibited a portable camera of novel design at the Great Exhibition, 1851. Fitted with a conical expanding cloth body, it was a collapsible camera of great lightness, and though taking pictures $8\frac{1}{2} \times 10\frac{1}{2}$ ins. it was only 4 ins. deep when packed up. The back of the camera was mounted on a sliding plate which could be clamped at any distance from the lens, thus enabling the operator to use lenses of different focal length.

In 1850 Marcus Sparling, Roger Fenton's assistant during the Crimean War, designed the first magazine camera, which was extensively employed by amateurs in the British Army. Ten sheets of sensitized paper could be stored in separate holders in a kind of magazine, each sheet being dropped after exposure into a receptacle underneath the camera.

In May, 1854, A. J. Melhuish and J. B. Spencer patented the first roll-film arrangement. The sensitive material (waxed paper) was rolled up on a spool, and after each exposure the paper was moved on and wound up on the receiving spool. The roll-holder was made in several sizes, the largest holding a roll for twelve pictures 12×15 ins., and it could be fitted to any camera. Frank Haes used the device for photographing animals in quick succession at the London Zoo in 1855 and 1856.

About the same time, and apparently independently, Captain H. J. Barr of the Indian Service invented a system of fixing sheets of sensitized paper on a band of black calico, leaving a space about 2 ins. between each paper. The band was rolled up on to one spool and unwound on to another in the usual way. The exposed pictures were taken off the band and developed separately. This was easier than Melhuish's and Spencer's arrangement, in which the paper roll had to be marked for each picture and cut up before development.

Cameras for Collodion Plates. Whilst the work of the professional portrait photographer was considerably eased by Archer's collodion process (1851–c. 1880) which provided a much faster sensitive material, to the landscape photographer the advantages of the process were almost outweighed by the colossal amount of equipment he had to take with him on his outings. As the plates had to be exposed and developed while the collodion was still moist, he needed—in addition to camera and tripod, and a choice of several lenses—a chest full of bottles containing chemicals for coating, sensitizing, developing, and fixing the glass negatives; a good supply of glass plates; a number of dishes, scales and weights; glass measures and funnels; a pail to fetch the rinsing water (and where there was none likely to be met with, the water itself!) and above all, a portable dark-tent in which all the chemical hocus-pocus took place.

Many photographers therefore engaged a man as porter, or pushed a wheelbarrow or a small hand-cart containing all the equipment. The more successful could afford a carriage, which in some cases simply served to convey the photographer and his equipment to the scene; in others it was completely fitted up as a travelling darkroom. Roger Fenton took with him to the Crimean War a horse-drawn van rigged up as a darkroom and living and sleeping quarters.

To obviate the need for a dark-tent, William Brown adapted in 1851 a camera designed by Frederick Scott Archer. This incorporated loose sleeves of black material through which the

ARCHER'S CAMERA. This was designed for the wet collodion process and incorporated the equipment for sensitizing the wet plates immediately before exposure. The image was focused on a ground-glass screen held in a frame which slid forwards and backwards on rails in the top of the body. Sleeves of black fabric at the sides enabled the operator to introduce his hands inside the camera to sensitize and process the plates.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

operator introduced his hands right into the body of the camera, where he carried out the sensitizing and processing in a gutta-percha dish. During the exposure, the dish was dropped into a detachable chamber at the bottom of the camera. Light was admitted through a small yellow window in the top of the camera.

This type was modified innumerable times for newer processes, and is father of the cameras still sometimes seen in use by old-fashioned tintype photographers at seaside resorts.

In Newton's camera, introduced the following year (1852), a chamber underneath the camera was divided into four compartments for the sensitizing bath, developing solution, rinsing water and fixing bath. The collodionized plate was attached to a rod which was moved along by rack and pinion and lowered into each of these compartments in turn.

In his patent of June, 1851, Fox Talbot also suggested a camera containing a glass cell or chamber into which the chemicals were to be introduced through a funnel and drawn off at the bottom by a stopcock. The mere idea seemed so fantastic to the photographic fraternity that it was dismissed as a joke, and Talbot's camera never went beyond the specification stage.

Large Cameras. During the collodion period the camera became both larger and smaller—according to the purpose it was intended for. Realizing the possibilities of photography as an independent art medium (in the 1840's photography had been largely in the hands of professionals whose main aim was to make a living out of daguerreotype portraiture) many amateurs took up the art and competed with each other in exhibitions. Naturally, the bigger pictures were more impressive and, as the slow albumen papers ruled out enlarging, the photographer had to use large plates from which he made contact prints.

Thus 10 × 12 ins. and 12 × 16 ins. were quite ordinary plate sizes. Francis Frith took some of his Egyptian and Palestinian views on 16 × 20 ins. plates. C. Thurston Thompson, the official photographer at the South Kensington Museum, had a camera 39 ins. square by 12 feet long. It ran on rails, and was first used in 1858 for reproducing the Raphael Cartoons, then at Hampton Court Palace, on glass plates 36 ins. square.

The largest camera before 1900 was made for John Kibble, a Glasgow amateur photographer, in 1860. It was mounted on wheels and drawn by a horse and took 36 × 44 ins. glass plates, each weighing about 44 lbs. The London optician Andrew Ross constructed a special lens of 13 ins. diameter and focal length 6 feet, at a cost of £170.

Small Cameras. A contrast to this monster camera were the binocular stereoscopic cameras introduced in 1856, when a great demand arose for photographs to be viewed in Sir David Brewster's stereoscope. These models took 3 × 3¼ ins. pictures and had 5 ins. lenses, and so were the first camera type to take successful instantaneous pictures of live subjects.

Realization of the new fields suddenly opened up by the binocular camera led to the construction of small cameras for taking single pictures. The first was Thomas Skaife's "pistol" camera (June, 1856), using plates of about 1½ ins. in diameter. It had a spring shutter worked by rubber bands which were released by a trigger (hence "pistol"), and a 1 in. Dallmeyer combination portrait lens working at *f* 1·1 or *f* 1·6—one of the fastest lenses ever constructed. Similar designs followed in the next few years.

Another miniature camera was Bertsch's "chambre noire automatique" introduced in 1860. It was of the fixed-focus variety (hence "automatic"); all objects beyond 40 feet were rendered sharp. This made a ground-glass

A WET-PLATE WORKER'S OUTFIT. This was a comparatively portable outfit and included, besides the camera and tripod, a dark-tent, a stool, and all the chemicals.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

unnecessary and, instead, Bertsch fixed a frame viewfinder and a spirit-level on top of his 4 ins. square metal box, which took pictures $2\frac{1}{4} \times 2\frac{1}{4}$ ins. The camera was made for the wet collodion process, but could be adapted for albumen or dry collodion plates which were stored in a changing box.

In 1864, the French engineer Dubroni introduced a small hand camera in which the sensitizing and developing of the plate were in fact carried out inside the camera body—a ruby glass globe contained in a box with apertures for the lens and for the introduction of the plate. Through a light-tight valve in another opening at the top the solution was introduced by means of a pipette, the camera then gently rocked to make it flow evenly over the plate, and the solution removed in the same way. The camera was made in five sizes, the smallest taking pictures 2 ins. square.

Other ingenious small cameras included C. Piazzi Smyth's model for photographing the interior of the Great Pyramid in 1865 and H. Cook's opera glass camera. Smyth's camera incorporated an ebonite silver nitrate sensitizing bath in which a 1×3 ins. plate (an ordinary microscope slide) was actually exposed through a 1 in. square window in one side of the bath. Cook's version had one lens for focusing, with a ground-glass screen at the rear, and another for taking with an attached magazine for 50 dry collodion plates. Piazzi Smyth stressed the advantages of the small negative over the larger, and described the process of enlarging the tiny plate.

All these ingenious instruments were, however, exceptions. The great majority of photographers worked with big plate cameras, still mostly of the wooden box type. The lighter bellows camera began to establish itself only very slowly, as photographers found a big bellows extension not rigid enough for the long exposures needed.

Multiple Cameras. In 1851 Antoine Claudet exhibited a multiplying camera which enabled the operator to obtain on one negative several miniature portraits, representing the same person in a different pose, or several people grouped together. The multiplying was performed by cross sliding motions of the dark slide by means of two racks. The resulting picture gives rather the effect of cinematographic shots.

Carte-de-visite photographers worked with a camera fitted with four identical lenses of short focus ($4\frac{1}{2}$ ins.); the camera interior was divided into four compartments, one for each lens. By exposing first one-half of the plate and then the other by means of a sliding plate-holder, eight small portraits could be taken on a plate $8\frac{1}{2} \times 10\frac{1}{2}$ ins. This facilitated the printing and multiplication of the small pictures, which were bought by the dozen by the sitter.

Apparatus for the Gelatin Process. The gelatin dry plate which came into general use in 1879–80 not only enormously simplified photographic technique, but also revolutionized camera design, reducing the photographer's equipment to approximately what it is today. The new negative material was fast enough for snapshots of moving objects, provided the cameras were small, quickly ready for action, and equipped with an instantaneous shutter. Manufacturers quickly responded, and during the 1880's and 1890's a mass of equipment of all shapes flooded the market.

Fast bromide paper had now made enlarging feasible and so quarter-plate and 4×5 ins. hand cameras established themselves as the most popular sizes for amateurs in the Anglo-Saxon countries, the equivalent on the Continent being the 9×12 cm. size. The characteristics of the new apparatus were compactness, simplicity in manipulation and light weight. In general, they can be classified into four main types: change-box cameras, magazine cameras, roll-film cameras, reflex cameras.

(1) Change-box cameras contained glass plates or cut films, usually 12 in number, in a separate change-box attached to the camera. This permitted a changeover in daylight, and the box was usually fitted with an automatic counter indicating the number of exposures made. Each plate was contained in a separate sheath, and after exposure a fresh plate was lifted into a soft leather bag attached to the top of the box, gripped with the fingers, and then manipulated into the focal plane. The prototype of this kind of change-box seems to have been that patented by H. Cook in May 1867 for use with his opera-glass camera.

(2) The magazine camera stored a number of plates or cut films (12–40) in a magazine or chamber inside the camera body, the plate being changed after each exposure by some kind of mechanism, which differs in almost every camera model.

LUMIERE'S MAGAZINE CAMERA. This model carried a dozen dry plates or films in suitable frames inside the body. The foremost plate was always pressed into the focal plane by a spring at the rear, and dropped into a compartment below by a suitable mechanism after exposure.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

WARNERKE'S FOLDING ROLL-FILM CAMERA. The lens panel moved on a monorail-like sliding bracket with a stabilizing rail, and the back incorporated a draw-slide and focusing screen, as well as the film rollers and transport mechanism.

In some magazine cameras the plates were contained in a grooved box, and dropped into position (or lifted up, as the case may be) by means of a rod with pincers through a slit in the camera. After exposure the plate was returned to its groove, and the next plate brought into position by a sliding movement of the magazine. In other magazine cameras, a dozen or more plates or cut films were stored in a chamber at the back of the apparatus. By various mechanisms, sometimes merely by shutting the camera ("shuttle magazine camera") the exposed plate or film was dropped to the bottom of the camera, and the next one pushed forward into the focal plane by a spring at the back of the magazine.

A magazine camera patented by Alfred Pumphrey in 1881, held separate pieces of coated film in frames. These were fixed by one edge to an endless band passing over two rollers, similar to the arrangement of pictures in a revolving stereoscope. By turning a knob, a film was brought into a vertical position behind the lens; another turn moved on the exposed piece and the next frame came into place. In 1882, Pumphrey introduced a camera taking 100 sheets of $3\frac{1}{4} \times 4\frac{1}{4}$ ins. film.

The "Frena" was the first hand camera to expose a pack of celluloid cut films, and was introduced in England in 1892. It held forty $3\frac{1}{4} \times 4\frac{1}{4}$ ins. sheets which were notched and inserted in a holder like a pack of playing cards.

(3) Roller-slides and roll-film cameras, which eventually superseded the change-box and magazine cameras, used flexible films instead of glass plates or cut films. The film was wound on two spools, the action of winding up the exposed portion unwinding a fresh portion for the next exposure. Originally the film was in a separate box, the roller-slide, which was made in many sizes for attachment to almost any camera. George Eastman popularized this idea in 1885 when he brought out his roller-slide attachment containing a paper roll coated with gelatin emulsion for 24 exposures. Three years later the roller-slide was loaded with nitrocellulose film for 48 exposures.

The Walker/Eastman roller-slide came close to Warnerke's of 1875. This was a very modern-looking folding camera which extended on a monorail.

The roll-film idea did not, however, become popular until much later when the growth of the amateur movement after 1880 created a demand and made mass production feasible, which brought down prices. Above all, the new D & P firms, which catered exclusively for the mass of amateurs unversed in photographic technique, took over the processing of these awkward long bands of negative material.

The camera which revolutionized photography in the 1890's and gave the greatest stimulus to amateur photography was the

EASTMAN KODAK ROLL-FILM CAMERA. The first amateur snapshot camera, the Kodak brought photography to the masses, very largely due to the developing and printing service that went with it. The camera took a paper roll with a stripping emulsion (later a celluloid film) and carried 100 exposures at one loading. It was also very simple to use: a fixed focus lens reproduced everything sharp from 8 feet to infinity, there was a single-speed shutter, and a single lens stop. When the film was finished, the camera could be sent back to the maker for reloading and processing of the exposed film.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Kodak, the first roll-film camera, brought out by Eastman in August, 1888. It was a simple small hand camera measuring only $6\frac{1}{2} \times 3\frac{1}{2} \times 3\frac{1}{2}$ ins. and weighing 2 lb. 3 ozs. It incorporated a roll of paper coated with a stripping emulsion on which 100 circular pictures $2\frac{1}{2}$ ins. in diameter could be taken. (Nitrocellulose roll film was used after 1889.) The camera had a rectilinear fixed-focus lens giving sharp definition of everything beyond 8 feet, one speed, and fixed stop. The apparatus was thus the embodiment of simplicity, and the price of 25 dollars (then 5 guineas) was reasonable. The Kodak's appeal to the amateur unversed in photography was enhanced by Eastman's stipulation that the camera be sent back to the factory for developing and printing of the film. It was returned loaded with a new film, together with 100 mounted prints, for a service fee of 10 dollars. Thus Eastman's slogan "You press the button, we do the rest" was put into practice.

(4) The single and twin-lens reflex cameras are classed as a separate group, for although they were variously made with change-box, magazine, or roll-film attachment, they are basically of different construction.

The principle of reflecting the image with a 45° mirror was already used in the camera obscura; the first to apply it to photography was Thomas Sutton, who patented his instrument in August, 1861. When making the exposure, the mirror was turned up by a handle. In 1888 S. D. McKellen patented the first reflex camera in which the mirror was automatically displaced during the exposure by being connected with a roller blind shutter.

The "Cambier Bolton" introduced in 1898 by W. Watson, London, made exposures automatically by pressing a button which raised the mirror and released the Thornton Pickard focal plane shutter. Speeds ranged from 1/20 to 1/1000 second.

R. & J. Beck constructed in February, 1880, the first twin-lens reflex camera. Both lenses were connected so that they focused simultaneously. The camera was a quarter-plate and, except for the roller blind shutter attached to the taking lens, it does not seem to have differed in any respect from modern twin-lens reflex cameras. Large numbers of other makes followed. Ross & Co.'s "Dividend" (1891) was the most advanced in design. Two models were made: one for 48 exposure Eastman roll-film and the other with a change-box containing 12 plates.

Pocket Cameras. Many of the cameras advertised as "pocket cameras" in fact were not. The first real pocket cameras for gelatin dry plates were Marion & Co.'s metal miniature camera of 1884 and the "Tom Thumb" produced by Ford of New York about 1890. The external measurements of the latter were $3\frac{1}{2} \times 3\frac{1}{2} \times 2\frac{1}{2}$ ins. and it weighed $7\frac{3}{4}$ ozs. The picture area was $2\frac{1}{2}$ ins. square. Like the Kodak, it was of the fixed-focus variety (everything beyond 8 feet was sharp) but it was made for plates, each in a separate plate holder.

Eastman followed up his Kodak hand camera with a pocket model in 1895, measuring only $2\frac{1}{4} \times 2\frac{7}{8} \times 3\frac{7}{8}$ ins., and weighing $7\frac{1}{2}$ ozs. Designed by Frank A. Brownell, this camera was the prototype of the "Brownie" class. It incorporated an important new feature, the daylight loading roll-film spool, taking a dozen $1\frac{1}{2} \times 2$ ins. pictures. In other respects, too, this camera pointed the way to modern camera design; it was made of aluminium, and the shutter was set and released by one button. Enlargements up to 12×15 ins. could be made from the negatives. Three years later Eastman effected a further improvement in compactness—the Folding Pocket Kodak, measuring $1\frac{5}{8} \times 3\frac{1}{2} \times 6\frac{3}{4}$ ins. This was a collapsible camera with bellows; when drawn out for use the lens-board was held rigid by struts.

The "Blocknote" made by Gaumont of Paris and introduced in 1903 was a highly finished folding pocket camera fitted with either a Rapid Rectilinear, a Zeiss Protar or a Tessar lens with an aperture of $f9$–$f6{\cdot}8$ according to lens. The $4\frac{1}{2} \times 6$ ins. plates were carried in single dark slides.

Freak Cameras. In January, 1881, Thomas Bolas designed for Scotland Yard a camera looking like a wooden box and another got up in the form of a book. These were the first of the so-called detective cameras. Manufacturers were quick to take up the idea and within a few years an absolute craze started for cameras disguised in the form of parcels, picnic baskets or a Gladstone bag—"an alligator-skin travelling handbag of innocent appearance". These were usually quarter-plate magazine cameras but before long detective cameras degenerated into toys of little practical value, got up in the form of opera-glasses, field-glasses, revolvers, guns, books, watches, or concealed in purses, walking-sticks, hats, cravats, or beneath the waistcoat. The lenses of these cheap cameras were poor, the pictures too minute to be of any use, and, like their forerunners the eighteenth-century cameras obscuras, disguised in walking-sticks and in book form, they can hardly be regarded as proper equipment. They do, however, show a steady trend towards the miniature camera, which as a scientific precision instrument did not arrive until 1924. A number of such ultra-small cameras have kept on appearing on the market up to the present day. Some were simple in design and scope, others reached a high standard of precision.

As a contrast to the small cameras in the 1890's, Anderson of Chicago constructed the Mammoth camera in 1900. It took pictures $4\frac{1}{2} \times 8$ feet—more than three times the size of Kibble's—and measured 9 feet high × 6 feet wide × 20 feet long when extended. The weight of the apparatus was 900 lbs. and, when the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

plate-holder was loaded, 1,400 lbs. Each glass plate, which had of course to be specially made and coated, cost £40, and the production of the print, £6 to £7. Two lenses had been specially designed for the Mammoth by Zeiss, one a wide-angle of 5½ feet focal length and the other a telescopic Rapid Rectilinear of 10 feet focal length. Obviously a camera this size needed special transport too: a railway truck 20 feet long pulled by a locomotive for long distances, and a furniture van for Chicago and district. The taking of a photograph required the services of fifteen men, and on the average an exposure of 2½ minutes. Five gallons each of developing and fixing solutions were needed. The purpose of the camera: the Chicago & Alton Railroad Co. wanted giant photographs for the Paris Exhibition of its new luxury St. Louis express to be taken in one shot instead of being made up from several views.

While the freaks in camera design—the outsize and sub-standard models—make very amusing history, the majority of amateur photographers in the period 1880 to 1930 worked with hand cameras or pocket cameras—to which were added in 1910 the vest pocket size. Practically all cameras were made of light-weight metal covered with black leather and were of the folding bellows type.

The 35 mm. Miniature Camera. The increasing volume of production of 35 mm. film for the cinema industry made its use economic for still photography. A few cameras appeared at the beginning of the twentieth century, employing this type of film. Examples were the Minnograph made by Levy-Roth of Berlin, taking 50 pictures 18 × 24 mm. on 35 mm. cine film, and an American camera designed and constructed by George P. Smith of Missouri in 1912; this latter 35 mm. camera took pictures 1 in. wide and 1½ in. long on perforated cine film.

In 1914 Oskar Barnack, a microscope designer employed by Leitz in Wetzlar, Germany, constructed the prototype of the Leica. This was at first only for his own use, in order to make test exposures on the small film he was using in a cine camera of his own construction. In 1924 Leitz put a modified form of this camera into production. The Leica of 1924 had a focal plane shutter which was automatically tensioned by the film transport mechanism, and used 5-foot lengths of 35 mm. film in daylight cassettes. Later models incorporated a coupled rangefinder for accurate focusing, and interchangeable lenses. The standard lens was a 5 cm. Elmar *f* 3·5, specially designed for the purpose by Prof. Dr. Berek. In fact, the resolving power of the Elmar was a long way in advance of the resolving power of the films of that day, and for many years the grain of the emulsion remained a serious problem to all photographers using miniature cameras. The importance of the Leica lies in the fact that it raised the miniature camera to a precision instrument. With it the era of the true miniature began, though for several years professional photographers and serious amateurs considered it a toy.

Soon other miniature cameras followed. Improvements in 35 mm. films and fine grain developers brought the quality of enlargements from miniature negatives on a par with those from larger picture sizes. In addition some of the makers of precision miniatures, from the Leica onwards, developed exclusive ranges of accessories and supplementary equipment to adapt the camera to every conceivable purpose, from amateur to scientific photography.

Candid Cameras. The 35 mm. miniature also proved popular for candid photography owing to its speed of operation. To permit even more rapid shooting, a few motorized miniatures also appeared. The most famous was first produced in 1936 and incorporated a spring motor. Pressing a button automatically exposed the picture, advanced the film and retensioned the shutter, permitting exposures at the rate of 8 per second.

At the same time wide aperture lenses made the miniature suitable for photography in poor light conditions. This, however, was not confined to the 35 mm. camera. In 1924, the Ernemann works, Dresden, brought out a 4·5 × 6 cm. and a 6 × 9 cm. plate camera, the Ernox, fitted with an *f* 2 anastigmat. This was followed in 1925 by the Ermanox, with an *f* 1·8 lens—the fastest lens ever made up to that time. This made possible snapshots of the stage, public dinners, and other indoor parties, without flashlight. Above all, since this camera was used in conjunction with fast panchromatic plates, the problem of grain which worried 35 mm. users at the time did not arise, and until that problem had been solved the Ermanox was the favourite camera for very poor lighting conditions.

Modern Reflex Cameras. The Rolleiflex, put on the market by Franke & Heidecke in 1928, has been the precursor of numerous similar twin-lens reflex cameras. It found immediate favour with all those who like to compose their picture on a focusing screen and have control over it during the exposure. There are two main sizes, 1⅝ × 1⅝ ins. (4 × 4 cm.) and 2¼ × 2¼ ins. (6 × 6 cm.), each taking 12 pictures on ordinary roll film.

As an alternative to the twin-lens reflex camera—with its limitation to a single focal length—a number of single-lens reflex cameras also appeared in the 1930's. Some of these took roll films, others 35 mm. film.

Present-day 35 mm. reflex cameras utilize pentaprism systems to permit observation of the screen image at eye level.

Camera Design Today. Fundamentally, present-day cameras differ little from corresponding types in use twenty years ago. They do, however, incorporate various refinements such as flash-synchronized shutters and double expo-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

sure lock or automatic shutter tensioning, rapid film transport levers, film indicators, better and faster lenses, and so on, to make them more foolproof and to increase their versatility. At the same time styling of cameras has become more streamlined, and pressed metal body frameworks have given place to metal or even plastic castings. Certain components were redesigned for easier mass production, rather than improved camera function, while improved testing methods were adopted to keep the standard of precision production up to the level of older hand-made cameras.

CAMERA LUCIDA. This is not a camera in the sense in which the word is now used. It is (or was) a four-sided reflecting prism used by draughtsmen and artists to enable them to draw outlines of objects in correct perspective. The prism generally has one angle of 90° and the opposite of 135°.

The artist holds the prism in position above a horizontal sheet of paper and sees a reflected image of the scene in front of him. He can then trace the outline by looking over the edge of the prism and referring what he has drawn to the reflected image.

The true camera lucida was invented in 1807 by Dr. William Hyde Wollaston, who also invented the meniscus lens. The camera lucida constructed by Dr. Robert Hooke in 1668 was an optical lens projection in a light room.

CAMERA MANUFACTURE

The demands by the photographer on his camera have long ceased to be confined to the optical and technical quality of his pictures. Nowadays the camera must be designed so that it is instantly ready for action, reliable under all circumstances and as foolproof as possible. The appearance of the instrument, and last but not least its price, are also of considerable importance in the design and manufacture of a camera.

Every design must to some extent be a compromise; high efficiency has to be paid for by higher retail price; the combination of a number of operations in one camera control results in bigger dimensions and greater weight of the camera which has to accommodate all the necessary mechanical linkages. So every advantage in one respect becomes a disadvantage in another. To deal with these problems, the designer requires imagination as well as technical ability.

Methods. The first cameras were craftsman-built instruments with brass-reinforced mahogany bodies and leather bellows. Even when parts were produced in quantity, they were assembled and fitted individually by skilled workers. These were drawn from the cabinet making and allied trades. Since relatively large plates and small aperture lenses were the rule, there was no need to work to close limits and as the demand was not great it could be satisfied by hand fabricated products.

Fast roll films and wide aperture lenses changed the manufacturing picture. These improvements made it possible to produce a new type of small—even pocketable—camera, and immediately increased the potential market. Small cameras had to be built to extremely fine limits and were more expensive to make, while the improved optical equipment added further to the cost. So to keep the price of the product down to an economic level the manufacturer has had to develop mass production methods to a remarkable pitch of perfection.

The design of the modern camera is naturally influenced by the manufacturing techniques available. It is an assembly of parts made of materials that lend themselves to mass production: machined or die-cast brass or light-alloy castings, sheet metal pressings or plastic injection mouldings.

Initial Stages. The specification for a particular camera is worked out in relation to the prospective demand and what the prospective buyer can be expected to pay. From rough drawings made at this stage the experimental workshop turns out a mock-up to form the basis for further practical discussions. This rough model is criticized, handled and where necessary altered until all concerned are satisfied with the principal features. Finally, an accurate prototype is built. This, apart from the fact that it is hand-made, is identical with the proposed production camera. Such prototypes call for a very high standard of craftsmanship and are the work of a special department.

Once the prototype is approved, the real work starts, and an immense amount of effort must be expended before the design can go into production. The factory building must be planned as a complete, organized whole so that everything moves steadily forward from the receipt of the raw material through the machining, assembly, inspection, packing and dispatch without unnecessary handling opera-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

CAMERA PRODUCTION LINE. The stages in which a camera comes into being vary in detail from manufacturer to manufacturer, but the general principle, as shown in a simplified form for a typical camera, is much the same. Top: *the body casting is machined and drilled for various apertures and screw holes.* Upper left: *Certain components like rangefinder housings and the like are stamped and pressed from sheet metal on large hydraulic presses, followed by plating and polishing.* Upper right: *Screws and mechanical components like winding levers and gear wheels are mass turned on automatic lathes and finished on milling machines.* Centre left: *Exposure meters are assembled and tested, and connected to the meter cell which is built into the body.* Centre right: *Viewfinder and rangefinder elements are assembled and tested before being installed in the camera.* Lower left: *The shutter is frequently supplied by a separate manufacturer, but undergoes careful speed and other tests for accuracy, reliability and synchronization before assembly in the camera.* Lower right: *Lenses also come from outside sources and are built into the models as complete single or multiple units.* Bottom: *Finally the finished camera undergoes thorough inspection with detailed optical and mechanical tests before being passed out and packed for sale.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

tions or bottlenecks. The various successive departments in the production flow are disposed either alongside each other or on adjacent floors of the same building so that the components can be passed from one stage to the next by the shortest route.

Components. As a first stage, every single component has to be drawn up accurately. Even a simple roll-film camera needs over 200 drawings of this type with almost 3,000 specifications of dimensions. A large camera factory must maintain extensive drawing offices and employ hundreds of draughtsmen to carry out this work alone for the various camera models.

When the drawings are finished, the next step is the building of machine tools, jigs and moulds for manufacturing the many individual components. This equipment must be very accurately made, for every error is magnified during production when passed on to the manufactured components. The required accuracy often has to be of the order of 1/1000 millimetre. These special tools are made by experts with many years of professional experience, and checked by precision microscopes for accuracy. For instance, the simple roll-film camera mentioned above may need over a thousand such machine tools made with the utmost accuracy.

A special department looks after the ordering of the raw materials—e.g., aluminium, brass, steel, leather, chromium, lacquers and varnishes. Only the highest quality materials are suitable for camera manufacture, and they are prepared for use only after being specially tested in the factory, mechanically, chemically, and under the microscope.

The production of the many individual components can now go ahead. A precision miniature may need over 600 such components, and many of those have to go through up to 200 different operations of manufacture and pass through twenty or more machines.

In the machine shops the main components are either cast and machined, or pressed in hydraulic presses into their final shape. Other components are turned on automatic lathes. Here the rod of raw material is fed continuously into the machine and shaped into bolts, screws, rivets, lens mounts, and other parts by a series of automatically controlled operations.

In another department automatic drills and cutting machines cut the various apertures, notches, and screw holes into the camera bodies. Milling machines finish many different forms of notches, slits and projections.

Finishing and Assembly. After all machining operations have been carried out, the parts pass on to the finishing stage. The finishing process varies according to the part. Some components are polished in special machines with diamonds, to produce mirror smooth surfaces, some are nickel or chromium-plated in the plating shop, while others are simply protected against corrosion for example, by lacquering or dipping in chemical baths.

The majority of the body components are leather covered by hand. There are inspection stages between all the individual manufacturing operations to check the accuracy of the single components and ensure that they will fit perfectly on subsequent assembly.

An intermediate warehouse stocks the finished parts in carefully planned groups and passes them on to the various assembly departments. Assembly methods vary according to the type of camera in question. At one time all assembly operations were carried out by hand, and they largely still are with very expensive cameras. The assembly operators are qualified by long training and experience, and their job is not only to put components together, but also to choose the components themselves of the right manufacturing tolerances (which are minute, anyway) to produce an assembly of zero tolerance.

With less expensive apparatus assembly operations are usually split into a number of comparatively simple steps requiring less highly skilled labour. It is also growing practice to produce sub-assemblies entirely automatically by machines. These are fed with components by special vibrator units which ensure that every screw, wheel, pressing, etc. arrives at the assembly point correctly orientated. The machines are self-checking, and automatically stop if a faulty component reaches the assembly stage, or if any of the assembly operations is not completed satisfactorily.

During assembly great care must be taken to prevent dust from getting into the camera, as the smallest speck in the wrong place can cause trouble later on.

The testing of components and of assemblies is frequently also carried out by machine. Modern electronic testing units can pass through screws and other small components at the rate of several thousand an hour. The machine rejects items that fall outside the tolerances laid down and at the same time counts up the number of rejected pieces.

Lenses and shutters are generally bought ready assembled from specialist manufacturers and fitted into the camera as a complete unit. Even camera manufacturers who make their own lens and shutter assemblies produce them in a separate department and deliver them complete to the general assembly shop where they are built into the camera body.

In either case lenses and shutters are retested before building into the camera, to ensure that they satisfy the exact specifications laid down in the production plan. This involves optical and alignment tests for lenses and speed tests for shutters.

Testing. The manufacture of the components and their assembly is checked at every stage but each camera has to undergo a final comprehensive test before it is released for sale. Here all individual operations are thoroughly

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

tried out, and the alignment and definition of the lens exactly checked. If any camera fails to pass the final test, it is returned to the appropriate point of the production line where the shortcomings arose. This test department is under the direct control of the management.

The cameras of a big manufacturer are sent out to all parts of the world. They therefore have to operate perfectly under any climate conditions. Constant functional tests are made in a refrigerator room at −20° F. and in a suitable oven at 120° F. to check the adaptability of the camera to temperature variations. Selected cameras are often placed in specially designed machines which tension and release the shutter as much as a million times to establish which parts break down first under heavy use.

Once the camera is released for sale it is packed in a special padded box along with the necessary instruction leaflets and passed on to the warehouse for dispatch. W.W.

CAMERA MOVEMENTS

Camera movements are all the different ways in which the film plane and the lens may be turned or moved from the normal position.

In a simple camera, the plane of the negative is parallel to the plane of the lens, and the optical axis of the lens passes through the centre of the negative at right angles. This arrangement is satisfactory for the general run of photography because such a camera reproduces scenes more or less as the eye sees them (after allowing for the fact that the light-sensitive surface of the eye is curved while the camera sees everything on a flat surface).

But the large professional stand cameras and technical cameras are almost always designed so that the angle of the planes of both the negative and the lens can be varied. The axis of the lens can also be shifted up, down or sideways in relation to the centre of the film plane. Every alteration made in this way produces a characteristic change in the appearance of the image.

Rise and Cross Front. This movement is provided by mounting the lens panel in guides so that it can slide to either side of, or above and below the normal axis. Only the lens panel is mounted in this way; there is no need for similar movements of the negative since the object is simply to displace one in relation to the other.

With the lens displaced in this way, the camera can look at things from above, below, or one side without being tilted at an angle to the planes of the subject. The objection to such tilting is that it produces an unpleasant appearance of distortion because the nearer parts of the subject are reproduced on a larger scale than those farther away.

The classic example of the effect of tilting the camera is the converging of the vertical lines in a photograph taken looking up at a tall building. But the same thing occurs with the horizontal lines when the camera looks at an angle at a line of buildings (when the lines are seen to converge as they run away from the camera). And the same effect can be noticed when the camera looks down on an object like a tall box. (In this case the vertical lines converge towards the bottom of the object.)

Distortion from the same cause affects subjects where there are no obvious vertical or horizontal lines—e.g., in the human figure. Here, in the absence of straight lines for comparison, the trouble is not so obvious, but it is there just the same, and the improvement is often striking when correction is applied.

The rise or cross movements are used in all circumstances like those quoted above, and wherever the camera has to look obliquely at the subject to show parts not properly visible in the normal square-on front view.

In practice, the camera is set up at the viewpoint which covers the subject from the required angle, but instead of being pointed at the subject, it is arranged so that the plane of the negative is parallel to the plane of the subject. The image is roughly focused, and then the cross front is used to slide the lens off centre to bring the subject into place on the screen.

As a result of this manœuvre the principal plane of the subject remains parallel to the negative plane and so is reproduced without distortion—the top of the box is visible, but the sides remain parallel; the belfry of the church comes into the picture without looking as though it were about to topple backwards, and the line of houses no longer narrows in violent perspective.

Used in this way, the rise and cross movements enable the photographer to control the perspective of subject planes inclined at an angle to the line of sight of the camera.

Back Swings. To provide the vertical and lateral back movements, the back is hinged or pivoted so that it can be swung about either side of the vertical and mounted on a base support which allows it to be turned horizontally about ten degrees each side of its normal position.

These movements are used to control the perspective of subject planes which are not at right angles to the camera sight line. If the back is swung to bring it parallel to the principal plane of the subject then parallel lines lying in the subject plane considered will appear parallel.

In practice, the camera is set up to look at the subject from the required viewpoint; the image is roughly focused, and the swing back is adjusted until it lies parallel to the plane of the subject in which parallel lines are to remain

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

parallel. After adjusting the lens panel in such a way that it is again parallel to the film plane (or as near parallel as possible) the image is then re-focused and the lens stopped down until the depth of field includes the whole of the subject.

The result is similar to that produced by the rise and cross movement (above) since in each case the plane of the negative is made parallel to the principal plane of the subject to correct the convergence of the important parallels.

In instances such as the above, if the rise and cross movements of the camera front, or the backswing of the camera, are individually insufficient, a combination of these can be used. When correction is made by means of the swing-back, so that the film plane lies parallel to that plane of the subject in which parallel lines are to remain parallel, then overall sharpness is regained by bringing the lens panel into a position parallel to the film plane. Care should always be taken that the camera movements are not used to an extent beyond which the lens is able to cope, and the corners of the image should always be examined carefully on the ground glass screen (with the lens stopped down to the aperture which will be used, if this is practicable).

CAMERA MOVEMENTS. Top left: *Horizontally swinging lens panel.* Top right: *Vertically swinging lens panel. Both these movements can increase overall sharpness.* Upper centre left: *Rising front for vertical image movement on the plate (e.g., to include the top of a building) without distortion.* Upper centre right: *Cross front movement for sideways image shift.* Lower centre and bottom: *Vertical and horizontal swing back for control of image proportions. The back may be hinged at either end, pivoted in the middle, or completely freely adjustable.*

In practice, if the degree of effective rising front used on, say, a tall building is such that the top of the building is not quite sharp when film plane and lens panel are parallel to the face of the building, this can often be corrected by tilting the lens panel upwards slightly. Such movement must be only slight, however, and it calls for a little stopping down, in order to retain sharpness over the entire building.

Swing Front. The lens is mounted in a panel which can be turned about both horizontal and vertical axes; it can thus be tilted down or up or turned from side to side. Ideally, the turning axes should pass through the rear nodal point of the lens. If this condition is fulfilled, the lens may be turned (within the limits of its field) without changing the position of the image.

Front swing is used to make the image of the principal plane of the subject coincide with the plane of the film. It is not necessary when the film plane, lens, and subject planes are all parallel—e.g., for a square-on photograph of a flat-fronted building.

When the principal plane of the subject is not at right angles to the camera sight line, some parts of the subject are nearer the lens than others. If the middle of the subject is focused sharply, then the ends will be out of focus. The ends can be brought into sharp focus if the lens is stopped down far enough to include them both in the depth of field. But this means losing light and prolonging the exposure.

The other way is to move one side of the lens forward to bring the near parts of the subject into focus, and the other side back to focus the distant parts—i.e., to swing the front of the camera in the same direction as the slope of the subject plane.

There are two principal uses for front swing. It can be used simply as a focusing device for giving a sharp picture of a sloping subject without the need for stopping down, or to increase the scope of the vertical back-swing.

If the swing front is used simply to bring the focal plane to coincide with the film plane when the back of the camera has been swung parallel to a sloping subject plane, the result is exactly as though the picture had been taken by a camera with a large amount of rise or cross front movement.

The same effect can be produced in a camera with a long format by focusing the picture on one half of the plate only—e.g., by taking a picture of a tall building on the bottom half of the plate. This is equivalent to using a camera of half the negative format with a very generous amount of rising front, or the equivalent combination of front and back swing.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

RISING AND CROSS FRONT. Top: *Sometimes the camera position cannot be altered and part of the image is cut off on the negative (thin frame and lens angle). The cross front shifts the whole image sideways, presenting a different view while avoiding distortion of perspective (heavy lines).* Bottom: *The rising front does the same thing vertically in order to include, for example, the top of a building or to reduce the foreground area without tilting the camera. Rising and cross front movements do not distort the image proportions.*

Combined Movements. Camera movements are used both independently and in conjunction.

The swing back and the rise and cross front movements may be used simultaneously to control perspective—generally to produce a more pleasing perspective although they may also be made to produce deliberate distortion.

The swing front alone has no effect on perspective; its purpose is simply to make the plane of sharp focus of the image coincide with the plane of the negative material. The object here is to avoid having to stop down the lens to bring both near and far ends of an inclined subject plane within the depth of field.

Front swing is often used alone—e.g., to bring foreground and background into focus without stopping down too much. It may always be used alone, in fact, for improving the depth of field over an inclined subject plane where there is no need to correct the perspective of the subject.

Back swing, on the other hand, is only rarely used without some degree of front swing. This is because applying back swing to compensate for camera tilt throws the plane of the negative out of register with the focal plane of the lens. Unless some front swing is added the photographer is forced to stop the lens right down and give a needlessly long exposure.

The amount of rise or cross front movement is decided by the position of the image on the focusing screen. The swing back can be set parallel with the principal plane of the subject by eye or measurement. The angle of the swing front can only be decided by careful examination of the sharpness of the image on the screen, preferably through a focusing magnifier.

Camera Movements in Practice. A photograph fully corrected by the use of camera movements is made as follows:

(1) The photographer selects the viewpoint which shows the subject to the best advantage

SWING BACK. Top: *When the camera points obliquely at the subject normal perspective effects appear, with near parts shown on a larger scale than distant ones. Swinging the camera back until it is parallel with the main subject direction, alters the perspective to give an isometric reproduction.* Bottom: *In the same way a vertical camera swing will straighten out converging verticals. In both cases the lens panel should be placed parallel to the film plane and the main subject direction, in order to retain overall sharpness of the image.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

SWINGING LENS. Top: *If some parts of the subject are nearer to the camera than others, the depth of field may not be sufficient to make the image sharp all over (thin frame). Swinging the lens in the direction of (but not parallel to) the principal subject plane makes near and distant parts equally sharp (heavy frame).* Bottom: *The same principle is used when the camera looks down obliquely on a subject of appreciable depth; a vertical lens swing increases the over-all sharpness. In both cases the image proportions are somewhat distorted, and the image shifts across the negative.*

for his purpose. Ideally this should be done by eye alone since it is the viewpoint and not the lens that decides the picture's perspective.

(2) The camera is set up with the baseboard level and back vertical and the image is roughly focused on the screen. If the image is too small, then the lens is changed for one of a longer focus; if it is too large, for one of shorter focus.

(3) At this stage lateral back swing is applied to bring the back of the camera parallel to the subject plane—e.g., the front of a building being photographed obliquely from one side. If the whole camera has been inclined at an angle—e.g., to look up at a tall building—vertical swing is used to bring the back of the camera vertical again. Lateral swing is adjusted by eye but vertical swing can if necessary be checked with a plumb line.

(4) The front swing is now adjusted to give the best distribution of sharpness over the plate. If the lens panel can be swung far enough to bring it parallel to the back and to the principal plane of the subject, then the whole of the principal plane can be covered sharply without stopping down the lens.

It may happen, however, that at extreme angles of combined front and back swing, the lens is so far off the common axis that it no longer covers the whole of the negative area. When this happens the front swing is reduced until there are no dark corners on the focusing screen—i.e., until the lens is once again covering the plate.

This change, of course, will also swing the plane of sharp focus so that it no longer coincides with the plane of the focusing screen—i.e., it will no longer be possible to get the image sharp at each side when it is sharp in the centre. So the lens must be stopped down to restore sharpness over the whole of the screen.

The image will now be fully corrected—i.e.,

SWING BACK AND SWINGING LENS. Top: *Use of the swing back to correct the perspective rendering can be combined with the swinging lens panel to increase the image sharpness. The distortions arising from the two movements will cancel each other out if the lens panel and camera back end up parallel.* Bottom: *In that case the swing back and swinging lens act together like a cross front movement. The effect of swinging the back and then the front is the same as that of turning the camera and moving the front horizontally.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

all vertical lines will be parallel to the sides of the focusing screen; the horizontal perspective will be acceptable; the relative proportions of near and far parts of the subject will appear natural, and the image will be sharp wherever sharp definition is called for. F.P. & V.G.

CAMERA OBSCURA. Literally, a "dark chamber". The term is applied to any optical device which forms a visible image of a scene on a screen set up in a darkened tent, room, or even a large box.

Except for the shutter, the camera obscura possesses all the essential elements of the photographic camera and can be regarded as its immediate ancestor.

From the early days of our civilization men appear to have known that light passing through a very small hole in the wall of a darkened room will form an inverted picture of the scene outside on the opposite wall. The image formed in this way is neither brilliant nor sharp. Making the hole bigger increases the brightness of the image but makes the definition worse.

Both the brilliance and sharpness of the image are greatly improved when a converging lens is used instead of a simple hole. The image can then be focused sharply on the screen.

EARLY CAMERA OBSCURA. The first published illustration of a camera obscura: a darkened room with a small hole in the wall at one side. Built in 1544 for observing an eclipse of the sun, it was illustrated in 1545 by Gemma Frisius.

Early History. There was no single inventor of the camera obscura; the principle had been applied as early as the eleventh century when it was used for viewing solar eclipses. A description dated 1550 refers to a lens, and one in 1568, to a lens and diaphragm.

The first really complete description of the camera obscura was given by Giovanni Battista Della Porta in 1558. On the strength of this he is usually regarded as the inventor.

Up to the seventeenth century the camera obscura was always a room in a house. One of its commonest uses was for producing "magical" effects. Charlatans, fortune-tellers and magicians employed the principle to mystify their clients. With its aid they conjured up miniature moving pictures of people and strange animals, often making them appear inside a glass of water or wine, the real action being staged outside the house.

With all such devices the observers had to be stationed on the inside of the dark chamber. A movable version in the form of a tent was mentioned in 1620, but it was not until the middle of the century that truly portable models appeared. These were commonly large (often collapsible) boxes equipped with a single biconvex lens, a reflecting mirror, and a viewing screen of oiled paper.

In this form the camera obscura was much used by artists as a guide to outline and perspective. It was often taken along by the eighteenth century tourist making the Grand Tour because it enabled those with no draughtsmanship to make sketches to illustrate the inevitable diary of the tour. It was, in fact, the equivalent of the present day snapshot camera.

Improvements. The camera obscura remained essentially unchanged from the end of the seventeenth century until the beginning of the nineteenth when Wollaston got over the serious spherical aberration of the double convex lens by using a meniscus. Chevalier took it a step further by using a reflecting prism with curved faces in place of the lens and mirror. No significant improvements have been made since.

In the common form of camera obscura, the observer stands in a darkened room or tent and an image of the external scene is projected on a white table-top before him. Immediately above the table there is a long focus lens with its axis vertical and pointing at the centre of the table. A mirror, set at 45° to the vertical is mounted outside the chamber above the lens so that it directs rays of light from the surroundings through the lens which focuses the image on to the viewing screen. In permanent types, the mirror can be rotated by the observer to scan the whole of the view outside. Permanent installations of this type are popular at seaside resorts where, for a copper or so, visitors can enjoy the scenery at their ease.

ARTIST'S CAMERA OBSCURA. Portable reflex box camera obscura with lens, first described by Johann Zahn in 1685.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

TABLE CAMERA. Guyot's table camera obscura of 1770 with lens O and reflex mirror N. The image was observed on the translucent surface E and was reversed left-to-right. The instrument made some attempt to combine semi-scientific utility with a semi-artistic finish to enable it to fit into a well-furnished drawing-room without appearing seriously out of harmony with the interior style of the period.

Artists have always made great use of the camera obscura and it was a natural step from tracing the projected image on a sheet of drawing paper to seeking for some means of fixing it with chemicals. Thomas Wedgwood about 1799 made the first photographic experiments with the camera obscura. Daguerre, who in his early days was a successful painter, made use of a camera obscura which is now in the possession of the Conservatoire des Arts et Métiers, Paris (Museum of Arts and Crafts).

CAMERA SHAKE. Blur is often caused, not by movement of the subject, but by movement of the camera at the time of exposure. This movement, generally referred to as camera shake, cannot be classified as neatly as subject movement. It depends on a number of variable factors: the human element; the camera; the focal length of lens; the shutter speed.

Easily recognizable characteristics of camera shake (distinguishing it from other types of unsharpness) are an equal degree of blurring of all parts of the picture, and frequently the appearance of two slightly displaced and somewhat unsharp images. This also covers the whole of the negative area; the image appears as if it had been slightly smeared over the film or plate.

The above applies to cameras with a diaphragm shutter. Camera shake with a focal plane shutter used at the slower speeds appears similar. At faster speeds (above about 1/30–1/60 second) image positions may look discontinuous or distorted across the picture area.

The Human Element. Some people can hold a camera steady at shutter speeds as slow as 1/10 second, others are troubled by camera shake even at a shutter speed of 1/100 second.

Part of the cause undoubtedly lies in the way the camera is held and how the shutter is released. The standard advice on holding the camera is to stand with the feet apart and steady the camera against the chest or face (depending upon the type of viewfinder). Before making the exposure some photographers find it helpful to take a breath, hold it and at the same time squeeze the shutter release steadily, rather than trying to click it erratically.

While this advice will do much to reduce serious camera shake it is always wise to avoid shake by taking advantage of any support available and using the fastest shutter speed possible.

The Camera. The design of the camera makes it more or less prone to suffer from shake. Generally, large, heavy, and square cameras give the least shake, and small, light, and streamlined cameras, the most. But the position, angle, and release pressure of the shutter control may have as much influence as the size and shape of the camera, and a camera that is free from shake when used at waist level may be impossible to hold steady when using the eye-level finder.

The Lens. Generally, the longer the focal length of the lens the greater the risk of camera shake. For the same amount of angular movement of the camera, the image formed by a 2× telephoto lens shows twice as much blur as the image formed by a normal angle lens.

The Shutter Speed. Photographs taken at fast shutter speeds are less likely to show blur than those taken at slower speeds. But the amount of blur is not necessarily in proportion to the shutter speed. If the blur is produced—as it often is—by a jerk that takes effect towards the end of the exposure, it may be just as pronounced at 1/40 second or faster as at 1/20 second.

Avoiding Camera Shake. Camera shake is very often to blame for blur that is put down to misfocusing, subject movement, or poor lens definition. Many photographers habitually accept a lower standard of sharpness than the camera is capable of, because they do not realize that camera shake is to blame.

The remedy is to make a number of exposures with the camera rigidly clamped, say, to the top of a heavy table.

This will show the standard of definition that the camera will give when there is no shake. The photographer should then experiment to find the shutter speed and methods of holding the camera and releasing the shutter that will give this standard of definition for hand-held exposures.

Trials carried out with a large number of operators show that the slowest shutter speed that the average photographer can use without undue fear of camera shake is about 1/125 second.

See also: *Holding the camera.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CAMERA SUPPORT

No matter how good a camera may be, or how accurately it has been made, it cannot yield really acceptable results if it moves during the exposure. Much of the poor definition obtained by amateur and professional photographers is caused by camera shake during the time the shutter is open.

Tripods. At shutter speeds slower than 1/25 second some sort of camera support is always essential. A tripod is undoubtedly the most effective answer to camera shake and should be used wherever possible; certainly whenever top quality results are required.

A tripod is a three-legged stand on the top of which the camera is fixed. Except for some of the larger studio models most tripods have folding or telescopic legs. There is nothing to beat the heavy wooden tripod for strength and rigidity. It is ideal for studio and indoor use but it is rather cumbersome to carry around and for this reason it is no longer popular with modern photographers who like to travel light. The necessity for portability has led to the lighter, collapsible type of tripod. Many of these are excellent, but some of the cheaper models are unsteady and useless.

The light folding type of tripod is not suitable for a heavy plate camera. A heavy camera needs a heavy tripod; there are even people who prefer to use a heavy tripod with a small camera rather than risk camera shake.

Methods for altering the height of a tripod vary according to the type being used. With a telescopic tripod it is only necessary to slide a section of the tubing in or out until it reaches the correct height. Folding tripods can be adjusted similarly by unfolding the legs to the height required. The permanent, studio types of tripod and some of the better metal types have an adjustable centre pillar.

Stands. The simplest type of stand consists of a solid, heavy base carrying a vertical pillar with a platform on top to take the camera. The centre pillar is adjustable for height and the platform can be tilted to point the camera up or down. In the more expensive versions of such stands all the movements are controlled by wheel or handle operated screws. One handle raises or lowers the pillar, another turns it to rotate the camera in the horizontal plane and a third controls the tilt of the top. The base of the stand may be on wheels with provision for locking them or putting them out of action when required.

A stand built for heavier duty consists of two vertical pillars mounted on a heavy low trolley. The camera is carried on a counterbalanced tilting platform between the two pillars. This type of stand has the advantage of allowing the camera height to be adjusted from the top of the pillars—which may be 7 or 8 feet high—down almost to ground level.

An even more elaborate type of camera stand is used in many commercial studios. This is the "all-angle" stand. It consists of a rigid H-section alloy chassis mounted on wheels. The chassis is designed to hold a large-diameter tubular column which carries the camera platform. The column is supported in a universally-mounted housing which allows it to be swung to any angle, and extended or rotated by control handwheels. Separate controls below the camera platform allow the head to be tilted in two planes. This type of stand is also used for clinical photography in hospitals where it allows the camera to be supported over the top of a prone patient at any angle. The stand is mounted on large castors which can be raised out of contact with the floor when once the camera is in position.

CAMERA SUPPORTS. **Left:** *Telescopic tripod with three extending legs. The tips may carry spikes (for rough surface) or rubber ends (for smooth floors). The tripod screw is ¼ in. (English) or ⅜ in. (Continental) Whitworth* **Right:** *Telescopic monopod.*

TRIPOD HEADS. **Top left:** *Normal ball and socket head adjustable in all directions, locked by a clamping lever.* **Top right:** *Tilting platform for larger studio and field cameras.* **Bottom:** *Pan and tilt head for a cine camera.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

STUDIO STAND. Stands for studio cameras have to be particularly solid to support the heavy camera and provide the full range of adjustments. Left: Generally the camera is mounted on a tilting platform which moves up and down along braced vertical columns. The whole stand is mounted on castors. Elaborate professional stands may have a separate platform (with ladder) for the operator as well as for the camera.

Heads. The camera must be attached firmly to the tripod or stand, and although there is always a plate or table with an attaching screw, this is not always satisfactory as it does not allow the camera to be set at an angle to the horizontal. The two most popular tripod heads, designed to allow adjustment of the camera angle, are the "universal" ball and socket head, and the pan and tilt head.

The ball and socket head, as its name suggests, is a ball with a tripod screw on top which can turn freely in a socket. A clamp can be tightened to grip the ball firmly in any position. This allows the camera to be tilted or angled as the user wishes.

Pan and tilt heads provide the same range of movements but are rather more versatile. They are primarily intended for cinematography and can be locked so as to swing (or "pan") horizontally but not vertically. This movement is impossible to achieve satisfactorily with a simple ball and socket head but it is essential for a cine camera to be able to scan a scene horizontally without any trace of wobble.

The panoramic head is basically the same as the pan and tilt head except that the axis of the panning mechanism has a scale engraved around it. This is calibrated in degrees from 0 to 360 and either moves with the head or is fixed on the stationary part. Panning of the camera can then be measured in degrees against a suitable reference mark engraved on the head. This is invaluable for photographing a panorama in sections when, after each successive exposure, the camera is panned to a fresh position. The angle through which the camera must be moved each time is equal to the angle of field of the lens (in practice, slightly less).

Other tripod heads are made for specialized subjects. The stereo head provides two alternate positions for the camera with a separation of 2¼ ins. for taking stereo pairs for three dimensional viewing. For astronomical photography there is the equatorial head which when driven by a special clock, keeps the camera following stars during time exposures. Another type of head available, particularly for twin lens reflex cameras, is designed to overcome parallax errors in sighting the camera; it allows the camera to be slid upwards, on a tube, to the exact height necessary to compensate for the parallax. This height is normally preset.

A special type of tilting head is useful for certain subjects such as still-life close-ups, copying, etc., taken with a heavy camera. The head there consists of two wooden platforms hinged book fashion at one end, and fitted with adjustable struts at the other to open the two halves to the desired extent. The bottom half is mounted on the tripod and the top carries the camera. The more the two halves are opened out, the greater the tilt; usually the adjustment possible is from 0° to 90°. Although this type of head permits tilting in only one direction, it is considerably firmer than a ball and socket or other type of tilting head.

Threads. All types of support provide a camera attachment in the form of a projecting screwed stud which screws into the camera tripod bush. The stud may be either ¼ or ⅜ in. Whitworth. Until fairly recently most British cameras were fitted with ¼ in. Whitworth tripod bushes, and Continental cameras with ⅜ in. Whitworth. Nowadays more and more British camera manufacturers are adopting the larger size. Many camera supports are designed to offer both sizes of fitting, either by means of a separate adapter or by a reversible head with a ¼ in. stud on one side and a ⅜ in. on the other. Separate adapters are available for adapting either size thread to the other.

Quick-release Fittings. To reduce the waste of time over fitting a camera to the top of the tripod by the normal screw, some camera makers supply a quick action holder for use with their own cameras. The holder has a tripod bush which allows it to be fitted onto the tripod head in place of the camera in the normal manner. With the holder in position the camera can be mounted on the tripod or removed from it in a second or two. The actual method of securing the camera body depends on the make of camera and most quick-release attachments have to be designed for a specific camera and cannot be used with other makes. However, universal quick-release fittings use

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

an attachment on the camera (as Digital Preservation Foundation, Chandigarh the tripod bush) which mates with a fitting on the tripod.

Gyro Supports. When the camera has to be supported on a moving base—e.g. on a vehicle moving over a rough surface, on a boat or in rocket-borne equipment—it may be mounted on a gyro-stabilized platform. This is essentially a camera support housing a spinning gyroscope driven by compressed air or electricity. The whole assembly is slung in gimbals which leave it free to turn in both horizontal and vertical planes. When the gyroscope is spinning, the support is held "straight and level" no matter how the carrier changes its altitude or direction. Simple versions use the gyroscope mounting merely to increase the camera inertia and so smooth vibrations and reduce camera shake. Alternatively, the gyro may be mounted separately and be used merely for feeding stabilizing signals to the control system of the entire vehicle in which the camera is carried.

In motion picture studios, the gyroscopic effect is applied to the camera support for another purpose. A gyroscope is mounted in the tripod panning head with its axis horizontal. When the gyroscope is spinning it opposes the panning movement of the head with a force proportional to the rate of turning—i.e. the faster the operator tries to move the head, the greater the resistance he has to overcome. The result is that the panning motion can be started, held steady or stopped smoothly and without sudden jerks or changes of speed.

A similar damping effect is obtained by incorporating an escapement gear with flywheel into the tripod head. The gear is coupled with the panning or tilting movement (or both) and is directly driven by the manual effort of moving the camera on the tripod.

Other Supports. A camera clamp can be a very useful support when it is inconvenient to carry a tripod. It is simply a pair of metal jaws which can be fixed to solid objects such as a table or a fence with a screw to hold the camera. Most of them incorporate a "universal" fitting to point the camera at any angle.

The pistol grip provides a steady single-hand hold, which is useful on both still and cine cameras yielding shake-free negatives at exposures considerably longer than are possible with the conventionally hand-held camera. A built-in cable release enables the shutter to be released by means of a trigger on the grip. The pistol grip is not, of course, suitable for time exposures.

SPECIAL SUPPORTS. Left: *Steadying chain fastened to camera.* Top right: *Chestpod.* Bottom right: *Gun stock holder for long-focus sports photography with miniature cameras.*

The monopod is a support consisting of a single leg which is used for keeping the camera still during slow exposures. Usually it is a telescopic tube which extends to about 5 feet. The camera is attached to the top and the foot has a spike or a rubber ferrule to stop it from slipping. Exposures of up to 1 second are usually quite safe.

The chestpod is a shortened variation of the monopod. It consists of a metal rod about 12 ins. long with a screw for the camera at one end and a leather strap at the other. The strap is then hung round the neck so that a downward pressure on the rod tautens it, and enables the camera to be held steady at eye level.

The gunpod is another light-weight portable support. As its name implies this is shaped like a rifle stock and fits comfortably into the shoulder. Many people use a gunpod to steady their cine cameras in the absence of a tripod and find it a reasonable substitute. This type of holder is also used for wild life photography with a miniature camera and a high-powered telephoto lens.

The chainpod is an extremely simple support that works quite well in practice. A piece of chain about 5 feet in length has a screw at one end which is fixed to the camera. The other end is then dropped on the ground and the user places his foot on it. By pressing the camera upwards the chain tautens and holds the camera steady. The chainpod can be used equally well with both eye-level or waist-level cameras. G.W.P.

CAMERON, JULIA MARGARET, 1815–79. English amateur photographer. She took up portrait photography at the age of 48 and specialized in close-ups. Many notables of the Victorian age sat for her, including Browning, Tennyson (a family friend), Sir John Herschel, Carlyle, Longfellow, Darwin, and others. Many of her imaginative compositions are rather pre-Raphaelite in style, in particular her illustrations to Tennyson's *Idylles of the King*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

(1875). She is considered today the most brilliant portrait photographer of the mid-nineteenth century. Biography by H. Gernsheim (London 1948). Autobiography: *Annals of My Glass House* (written 1874, published in Gernsheim's biography).

CANADA. Photography made a very early appearance in Canada. News of the invention of the daguerrotype in 1839 was eagerly reported in the Press and within fourteen months of the invention the *Quebec Gazette* (dated 13th October 1840) recorded an account of a demonstration of portraiture by Messrs. Halsey and Sadd at the address of a M. Grace, rue St. Joseph, Montreal.

Another recorded reference to the beginnings of photography is to be found in the Montreal Directory for 1842–3, in which is entered: "Prosch (G.W.), photographer, Place d'Armes, East Side". And in the *Minerve* of 28th October 1847, a reporter refers to a M. Desnoyers who proposed to devote his time to daguerrotype photography.

The demonstration of 1840 is most likely the earliest use of photography in Canada.

Commercial and Technical Progress. Perhaps the most important and influential firm in the practice of photography from its early establishment onwards in Canada was that founded by William Notman in Montreal in 1856. At the start daguerreotypes and ambrotypes were made. A notable work was a series of photographs showing the setting up of the Victoria Bridge stage by stage, which together with a series of views of Canada East and Canada West were presented to the then Prince of Wales (later King Edward VII) in bound form when he officiated at the opening of the bridge in 1860.

Then followed the use of wet plates and the popular *carte de visite* size portrait, and when dry plates came into use in 1880 W. Notman started to make them in the studio. But his output was not great enough to meet requirements, and he arranged with Stanley Bros. of Lewiston, Maine, to open a factory for their manufacture. When platinum paper was introduced in 1890 he obtained a printing machine from the Platinotype Co., London, and used this printing-out process until its discontinuation in 1914.

The London *Photographic News* (reported in the *Canadian Illustrated News* of 23rd July 1870) confirms W. Notman as one of the leading photographers of his time, and also mentions an associate of his, Frazer, as well as Inglis of Montreal, and Messrs. Sheldon and Davis of Kingston. Their work featured in exhibitions throughout the world and received much favourable comment and recognition by medals and other awards. Notman's work was forgotten until some of his portfolios were published recently by a leading Canadian magazine.

Manufacturing. When the dry plate was introduced Notman first approached British manufacturers to set up a plant in Canada, but he met with no success and this led him to make the arrangements with the American firm of Stanley Bros. referred to above. Then in 1900 the Canadian Kodak Company, Ltd., was formed in Toronto, and from its small beginnings has grown continuously. In May 1963 it was announced that a new expansion programme was being undertaken on the 45 acre site to increase facilities to 1,040,000 square feet, which would place Canadian Kodak in a position to supply all their Canadian requirements from Toronto.

Currently 90 per cent of the black-and-white film sold by Kodak in Canada is made in Toronto and there are large production figures for paper, motion picture films, X-ray materials and graphic arts film. Kodak colour- processing plants exist in Toronto and at the new Pacific Coast plant in North Vancouver.

1963 has also seen the opening of a manufacturing plant for Ansco of Canada Ltd. and the assembly in Canada for the first time of many products of Argus design.

Bell and Howell (Canada) has for some time been active in the assembly of cameras and projectors in Toronto. Since 1952 high precision optics and instruments have been produced in Midland, Ontario by Leitz (Canada) and many of the current lenses for the Leica camera have been designed and manufactured there. The company also maintains assembly lines for Leica cameras, and has been particularly active in the design and production of optical instruments to special industrial and government specifications.

Consumption of photographic materials is split evenly between amateur photographers and all professional fields. Canadian production of photographic materials approximates $30 million annually whilst the retail sales of photographic equipment and materials, including processing, approach $200 million. Photographic imports since 1953 have doubled, the 1961 value being placed at $52 million.

Associations. Most provinces have their own professional associations, and the Professional Photographers of Canada are making progress toward affiliation of the several groups. The greatest obstacle is distance.

Formed under Federal Charter in 1948, the Professional Photographers of Canada was formerly known as the Commercial and Press Photographers' Association of Canada, and its zeal in stressing education in photography both to photographers and to the general public has been exemplary.

This association has for 17 years exhibited its annual National Print Show from coast to coast in an endeavour to interest the public in fine photography. Within the ranks of its own membership it has since 1954 conducted an Annual Short Course at the University of

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Western Ontario, covering a wide range of professional techniques under the instruction of leading Canadian and non-Canadian professionals. Members travel to this course from all parts of Canada, often thousands of miles.

The Professional Photographers of Canada also organize at regular intervals a series of lectures of 8 to 10 weeks on a weekly basis on subjects allied to photography, including optics, and colour. The 1963 series was on visual communications and photography, and was held at the Doon School of Fine Arts, an affiliate of the University of Waterloo.

The Canadian Photographic Trade Association, concerned primarily with matters within the industry, was founded in 1956. It also maintains an active interest in the promotion of photography by its assistance with public exhibitions and the preparation of material for general publication.

One nation-wide association which has proved very successful is the Colour Photographic Association of Canada, which has a membership of over forty clubs. The Association is devoted solely to colour photography, and holds national conventions, regional meetings and a full complement of association activities, and provides instructional aids for the benefit of its member clubs.

The Federation of Canadian Amateur Cinematographers has been formed to serve the interest of amateur motion picture workers in Canada and embraces fifteen amateur cine clubs within Canada. It concerns itself actively with film festivals in Canada, and internationally through Union Internationale de Cinema Amateur, of which it is a member.

Activities. It has been estimated that 70 per cent of the population use cameras, and that over 250 million pictures are taken each year. Automation in cine and still photography has been a stimulus to the more casual type of amateur photographer and has led to an increase in camera club memberships.

Whilst camera clubs are active across the country, there is no central association to absorb them, although steps in the past few years to form a federation of the many clubs in the Toronto area are setting a pattern for possible extension.

The Toronto International Salon of the Toronto Camera Club, founded in 1888, is the oldest Salon of Photography on the North American continent and still continues successfully today.

Present-day Photography. Contemporary use of photography is probably as extensive in Canada as anywhere in the world, particularly with regard to commercial, industrial, and scientific applications. Uses rather special to Canada are in the aerial surveying of the country, much of which has not previously been mapped, and in the production of mail order catalogues.

A few Canadian photographers of today have established for themselves international reputations, especially in the field of portraiture.

Motion picture production in Canada has brought in a great many international awards, particularly to the National Film Borad. With the emphasis on documentary, training, educational and industrial motion pictures, and serving the most widespread TV network in the world (4,000 miles from Newfoundland to Vancouver Island), motion picture photography is a prolific recording and artistic medium in Canada.

Statistics indicate that over 44 million feet of 16 mm. film and 20 million feet of 35 mm. film were processed in Canada during 1961, and the country is well supplied with film libraries, usually under the auspices of provincial governments, education departments and the Natianal Film Board.

The vicinity of the United States, with its large photographic press, has made the publication of magazines for the amateur photographer in Canada a project of some hazard. Additionally the advertising revenue necessary to support production costs is very limited in a country of 18 million inhabitants. The monthly publication *Photo Age* serves the amateur field.

Many Canadian newspapers carry weekly photographic pages and supplements, and weekly radio programmes by well-known photographic personalities have been regular features for some years. With the opening of Toronto's first private television station in January 1961, the first of several weekly series for amateur photographers began. This was eventually followed by a similar series on the Canadian Broadcasting Corporation's television stations. These must rank with the first programmes of this type seen anywhere on a regular basis.

R. de L.G. & G.M. (J.B.W.)

CANADA BALSAM. Viscous fluid resin obtained from the Balsam Fir of North America. The liquid form of the balsam slowly changes into a hard crystalline solid with a refractive index almost exactly equal to that of glass.

It is used for cementing together pieces of optical glass—e.g., the component parts of a lens—to make an invisible joint. It is also used in some negative varnishes.

Solubility: Insoluble in water; soluble in xylol.

CANDELA. Photometric unit of luminous intensity (formerly known as candle power) and defined as 1/60 of the luminous intensity of 1 sq. cm. of a black body at the temperature of solidification of platinum (1,769° C.). Also known in common usage as the candle, and approximately equal to the former international candle. The candela is now a standard international unit.

CANDID PHOTOGRAPHY. Term coined by the art editor of the *Weekly Graphic*, London, on 11th January, 1930, for some revealing photographs of politicians, taken by Dr. Erich Salomon. A candid photograph is a picture of a person, or persons, engaged in some natural, believable activity. It is unposed and is often taken without the knowledge of the subject. Very early in the history of photography inventors began constructing—and sometimes marketing—cameras that the photographer could conceal about his person to enable him to take photographs without being detected. But true candid picture making only became really popular with the development of the modern miniature camera.

With the advent of the large circulation illustrated magazines throughout the world, in the 1930s, photo-journalistic work became well known. A high percentage of such work is of a candid nature.

Many photographers have achieved world fame for their candid photography. Notable names include Henri Cartier Bresson, Alfred Eisenstaedt, W. Eugene Smith, Robert Capa, and Margaret Bourke-White.

There are two ways in which the candid approach is helpful: for scenes of everyday life including or featuring people and children, engaged in their everyday activities and for procuring natural and unaffected portraits of subjects who would be awkward and self-conscious if they knew they were being photographed.

UNOBSERVED SHOOTING. A reflex camera is particularly easy to operate without attracting attention. Top left: *Camera hidden under coat and operated through cut-away pockets.* Top right: *Shooting backwards underneath the arm.* Bottom left: *Swing-round technique of focusing in one direction and swinging round to shoot subject.* Bottom right: *One of several ways of shooting sideways or round the corner.*

Camera. The best camera for candid photography is the 35 mm. miniature because it is small enough to be used unobtrusively and its operation is as nearly automatic as coupling and interlocking can make it. At the same time many workers prefer the twin lens reflex because it can be used at waist level and the photographer does not need to advertise his intentions by looking at the subject. The miniature user, however, can make use of a long focus lens to let him work at a distance from his subject and thus stand a better chance of getting his pictures without being noticed.

A camera with automatic film transport is better than one that has to be checked visually at the risk of attracting the attention of the subject.

Very fast shutter speeds are not needed; probably the most useful speed is around 1/100 second although there are occasions when a short time exposure may be unavoidable.

The quieter the shutter the better; even the slight click of a high grade shutter can be embarrassingly evident. Indoors, in fact, it may be worth while using a supplementary silent shutter in front of the lens of the type made for studio portraiture and nature work.

Lens. Each type of lens has points for and against it. The long focus lens lets the photographer shoot from a safe distance, but it calls for accurate focusing and sighting because it has a narrow angle of view and a shallow depth of field. A wide angle lens can be set to give a deep zone of sharp focus and includes so much of the scene in front of the camera that it can be sighted quite casually. The virtues and shortcomings of the normal camera lens lie midway between these extremes. The photographer who can afford all three will find each one useful at different times.

On most occasions a wide aperture lens is a decided advantage because it permits a fast shutter speed to be used.

Lighting. The candid photographer must be prepared to make do with the existing lighting. About the only control he can exercise is to change his position to photograph the subject from a more favourable angle. There is one exception to this rule: when taking photographs in the dark by invisible lighting such as infra-red.

Viewfinder. A reflex viewfinder would appear to be ideal for candid photography, yet many of the top men use a miniature and a direct vision finder with complete success. The reflex finder allows the photographer to point his lens at the subject while he looks away at right angles, and the same thing can be done with the angle type of supplementary finder. These aids help to make candid photography easier for people who cannot acquire the art of direct shooting.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Technique. The candid expert rarely tries to conceal or disguise himself or his camera. He simply acquires the knack of making himself unobtrusive. This may be done in a number of ways:

(1) By wearing conventional dress with no eccentricities.

(2) By moving and working in a slow, leisurely fashion.

(3) By misdirection—i.e., by pretending to be interested in anything but the subject. This means not only looking, but turning, in another direction.

(4) By taking up a position between the subject and the strongest light source. (This makes it harder for the subject to see what he is up to.)

(5) By keeping his camera either out of sight, or pointing in another direction until the last minute.

As far as possible all the necessary adjustments are made to the camera before the photographer goes into action; he sets the shutter speed and lens aperture and focuses the camera for the approximate working distance. Then he approaches the subject casually and chooses the position that gives him the best view and lighting of the subject. If the subject is unlikely to move out of range, the photographer settles down for a while before starting to shoot to disarm suspicion. Soon his presence is accepted and ceases to arouse curiosity and he is free to take his pictures without the subject's knowledge.

The candid technique is particularly useful for getting natural pictures of children. It is not necessary for the child to be unaware that there is a camera pointing at him; the photographer simply waits until the child loses interest in the camera and turns all his attention back to his game or occupation.

For stunt picture series in magazines, elaborate ways of concealing the camera have been used—even by installing façades (such as half-silvered mirrors) in public places. F.P.

CANDLE METRE. Unit of illumination also known as a metre candle, or a lux. It is the illumination of a surface one metre distant from a light source of one candle power.

See also: *Light units.*

CANDLE METRE SECOND. Photometric unit applied to exposure, now usually called a lux-second.

See also: *Light units.*

CANDLE POWER. Obsolescent term for luminous intensity. The present international unit is the candela. Frequently (but incorrectly) also applied to the unit of light intensity itself, e.g. by quoting a source to have *x* candle power.

See also: *Light units.*

CANVAS PRINTS. Canvas and other similar fabrics can be treated so that it is possible to print them with a photographic image. The printing may be carried out by contact printing in daylight or artificial light or by enlarging.

See also: *Fabric printing.*

CAPA, ROBERT (Robert Friedmann), 1913–54. Hungarian born war photographer and founder member of Magnum Group. Photographed five wars in eighteen years: the Spanish Civil War, the Japanese invasion of China, World War II, the Arab-Israel conflict, and the Indochina War. Killed in May 1954 by a landmine in North Vietnam while photographing French combat troops.

CAPACITOR FLASH GUN. Flash gun in which the bulb is fired by the discharge from a small condenser. The advantage of the system is that it operates even when the dry battery which charges the condenser in the first place is getting weak.

See also: *Flash equipment.*

CAPTION. Some pictures are no use without a caption, some are better if they have one, and others do not need one at all. News, sporting, and technical photographs need captions to describe the people or things they show. And photographs that aim at conveying an idea—artistic, abstract, or humorous—generally need a caption to make the idea clear. Then there are the examples of pure photography, pictures which tell the whole story without any help from the caption.

Photographers are not expected to write the captions for pictures they submit for publication—caption writing for the press is a skilled technique that is best left to the editorial department. But editors do need the material for making the captions. Unless they get the right information with the photograph they are unlikely to use it.

Essential Information. First they want to know who took the photograph. (If the sender did not take it himself, he will have to convince the editor that he owns the copyright or that he is entitled to sell on behalf of the owner.) So the sender must always attach his name and address to the photograph. It is always safer to write or stamp this on the back of the print because the covering letter might be mislaid and labels get unstuck.

Then editors want to know who or what the photograph is about, where and when it was taken, and what are its points of interest from the angle of their particular readership. This means giving complete names, dates, and a short write-up of the facts. All this can go on a typed sheet that can be stuck along one edge of the back of the print and folded over to protect the surface.

CC-0. Agastya and Digital Preservation Foundation, Chandigarh

If ever the photographer is asked to write the caption himself, the rules are simple. Do not include any information in the caption that is already clear in the photograph. Tell the reader anything that is not obvious in the photograph but which he must know if he is to be interested in what does appear. Make sure that the meaning is clear, even if it involves writing a longer caption.

Whenever a photograph is taken with an eye on subsequent publication, all the relevant information should be written down at the time. If any people are featured in the picture it may be necessary to get their written permission to reproduce their portraits—or the promise of it—and their names and addresses. It may be extremely difficult or even impossible to get these facts at a later date.

Creative Captions. So much for the pictures that must have a caption if they are to mean anything. But what about the pictures that are understandable without any caption but can be improved by a good one?

These are the difficult captions to write for the simple reason that they need imagination. They are creative. They have more to do with fancy than fact. They are no longer bald descriptions; they are personal comments. This sort of caption starts before the picture is made. It starts with the idea behind the picture. That idea is the germ of the caption; if there was no idea it is unlikely that there can be an effective caption.

Nevertheless, when it comes to the literary side of writing such captions, editors often prefer to do that themselves.

Labels. But considerable thought is often given to pictures that do not need a caption at all. When the photograph tells the story itself, all the caption it needs is something to take the place of a reference number—a label. A straightforward figure study or landscape is not improved by an obscure title when all it requires is a label. Nothing is gained by trying to give a suggestion of hidden significance to a picture that ought not to want it.

A label is in fact a bare title or description, such as *Derwentwater*, or *Collie dog and pups*, without embellishments.

A human portrait should be sufficiently interesting in its own right to be able to do without such forced afterthoughts as, *Soliloquy*, *Meditation*, *Thoughts in Idleness* and similar stale clichés. A figure study that cannot be sold without a fanciful caption will not be sold with one either. The task of the caption here is simply to identify the picture, and very simple labels will suffice: *Norah*, *Dutch Girl*, *Model Resting*.

The same applies to landscapes. It is impossible to make up for lack of beauty in a picture by adding a poetic caption like *Evening's Glory*, or *The Knell of Parting Day*. And to go even further and add a complete quotation either distracts attention from a good photograph or focuses it on a bad one. Once again, the caption should be simple and unselfconscious: *Cotswold Cottages* not *Mid Rustic Charm*, and *Ice on Wire Netting*, not *Nature's Handiwork*.

For those who must have rules, the following general advice can be given. Be sincere. Be clear rather than simply brief. Be honest. (Do not use a caption to give a photograph a meaning that was not intended when the picture was taken.) Captions sell pictures, but the pictures have to be worth buying. F.P.

CARBOLIC ACID. Solution of phenol. Once widely used disinfectant and preservative—e.g., of gelatin and organic mountants.

CARBON ARC LAMP. This was the earliest form of commercial photographic lighting. It is produced by passing an electric current through two carbon pencils with their points in contact and then slightly separating the points. This process is known as striking the arc; it creates a flame of burning gas between the ends of the carbons. The gas itself and the ends of the carbons glow with an intense brightness, forming a compact light source which is particularly suitable for projectors, floodlights, and other forms of controlled illumination.

Improvements. The simplest type of arc lamp is known as the open or low-intensity arc. It contains an excessive amount of red light and consumes carbons at a relatively high rate. A great improvement was made by enclosing the arc in a glass globe with only a very restricted inlet for air. The enclosed arc tends to consume the air faster than it can enter the globe with the result that the pressure in the globe falls. Under the reduced pressure the gap between the carbons can be increased to as much as 2 ins. (5 cm.), giving a long, violet flame of high actinic power. Carbons last much longer in the enclosed arc than in the open type; the burning rate may be as low as ¼ in. per hour in a lamp of average size.

Carbon arcs have been greatly improved in colour temperature and intensity by using cored carbons incorporating certain metallic salts, and by increasing the current loading of the carbons. A combination of the two methods forms the basis of the modern high intensity arc used in television studios, film studios and cinemas.

Consumption. A typical low intensity arc consumes around 2 kilowatts with an efficiency of about 15 lumens per watt, whereas a high intensity arc may consume as much as 13 or 14 kilowatts with an efficiency approaching 30 lumens per watt—i.e., almost twice as much light as the low intensity arc for a given power consumption. High intensity arcs with a working current of 200 amps. or even more are used for film studio lighting.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Electrical Characteristics of the Arc. The carbons must be brought into contact and then separated to start or strike the arc. At the instant of contact the resistance between them is practically nil, so the circuit must include some form of ballast to limit the flow of current. In D.C. arcs the ballast consists of a variable resistor; in A.C. arcs a choke, or better still, a reactive transformer, is used.

Once the carbons are separated and the arc is struck, the resistance varies according to the current passing and the type of arc. The important figure in calculations is the voltage drop across the arc which may vary from twenty or thirty to as much as 160 volts. The supply volts must be greater than the arc volts, the difference being dissipated in the resistor (unless the arc is being run on A.C., when a step-down reactive transformer may be used). Where two or more arcs can be connected in series, less ballast is needed and the efficiency of the system rises in consequence.

A.C. or D.C. When an arc is fed from a D.C. supply, the positive carbon burns away to form a hollow crater from which most of the light is emitted. This crater is treated as the light source when focusing the arc. The carbons are inclined at an angle so that the maximum amount of light is radiated in the most useful direction.

When the arc is fed from an A.C. supply, each carbon is alternatively positive and negative so that the tips of both glow with the same intensity. Sometimes both carbons are sloped to form a "scissors" in which both craters point towards the desired direction. But the twin source still remains as a defect of this type of arc.

When cored carbons are run on either D.C. or A.C. at a high current density—up to 10 amps. per square millimetre—the main light no longer comes from the positive crater; it is radiated by a ball of incandescent gas between the carbons. This ball of gas approximates to a point source and has a colour temperature almost equal to daylight. This type of arc, when produced by an alternating current, shows a reduced tendency to flicker at the frequency of the supply and it is for this reason the only A.C. carbon arc that is suitable for projection or film studio lighting.

SCISSORS ARC. This is an A.C. arc; craters are formed in both carbons. When used in projectors, etc., both carbons must be directed towards the condenser or other light collection system. The most efficient control is a choke. The current is increased by withdrawing the iron core from the windings.

CARBON FEEDING METHODS. Top left: *Stirrup feed; lifting the counterweight allows the carbon to drop.* Bottom left: *Motor feed; the speed is adjusted by a potentiometer feeding the brushes, thus controlling the feeding rate.* Right: *Solenoid feed; as the current decreases, the upper carbon drops.*

Feeding the Carbons. As the carbons are burned away in the arc, they must be closed up to maintain the gap or the arc will eventually go out.

In the simple arc lamps fitted in lantern slide projectors and flood lights the carbons are individually adjusted by hand wheels on the outside of the lamp house, the operator observing the effect on the arc through a deep violet or red window.

Arcs used for overhead street and public lighting are controlled by a solenoid which automatically strikes the arc when the current is switched on and maintains the gap between the carbons.

The high intensity arcs used in film studios and cinema projectors burn at a very high rate and so have to be fed automatically by a motor connected across the arc gap. As the carbons burn, the gap widens, the volts across it increase, and the motor speeds up. As the carbons approach each other, the volts across the arc fall, and the motor slows down. By a suitable choice of reduction gearing, the carbons can be kept moving in fast enough to compensate for the amount of carbon consumed in the arc.

CARBON FILAMENT LAMP. Lamp in vented by Sir J. W. Swan and Thomas Alva Edison; it was the earliest type of incandescent electric filament lamp. The light was given out by a fine filament of carbon heated by an electric current and mounted in an evacuated glass bulb. In the absence of oxygen, the filament simply glowed instead of burning away. It gave a distinctly red light and was less efficient than the gas-filled tungsten filament type.

See also: *Artificial light history.*

CARBON PROCESS. The carbon process is one of the control processes for making positive prints. Paper coated with a layer of carbon or coloured pigment suspended in gelatin is sold as carbon tissue. This is sensitized, and exposed under a negative. The exposed gelatin becomes insoluble in water, therefore the pigmented image remains after the paper is "developed" by washing in warm water to remove the soluble gelatin.

For many years the carbon process was favoured for exhibition prints, and the best professional portraiture. The process is capable of giving prints of great beauty, and it can reproduce a wide range of tones. Prints can be made in a great variety of colours and they have the additional merit of being permanent. R.M.F.

History. In the 1850s, numerous attempts were made to devise a cure for the fading of positive prints, due chiefly to inadequate rinsing. Alphonse Louis Poitevin (1855), John Pouncy, Adolphe Fargier and others invented methods of making positive prints in permanent pigment. The principle involved in most methods was to colour with carbon—one of the most unalterable substances in nature—gelatine, gum, or similar organic substances made light-sensitive with potassium bichromate, which hardens in light. "Development" consisted in washing away the insoluble parts of the picture. These early methods were deficient in half-tone. Carbon printing was successfully introduced with (Sir) Joseph Wilson Swan's perfected process in 1866 (patented 1864). The firm of Mawson & Swan in Newcastle-on-Tyne supplied ready-made carbon tissue consisting of a film of gelatine containing finely powdered carbon, spread on paper. The tissue was sensitized by the photographer with a solution of potassium bichromate and, when dry, exposed under a negative. The face of the carbon tissue was then attached to a temporary paper support and soaked in warm water which removed the original paper backing and the soluble parts of the gelatine which had been protected from light by the more opaque parts of the negative. The insoluble gelatine image remaining on the temporary support was then dried, and as the picture was laterally reversed, it had to be transferred a second time to its final support. The picture was in relief, the gradations of the negative being represented by corresponding degrees of thickness in the coloured gelatin.

Swan's carbon process was widely practised under licence by firms producing large quantities of prints, and is still in use.

A satisfactory carbon process on a different principle was patented by Poitevin in 1860, based on the hygroscopic property given by light to a coating of perchloride of iron and tartaric acid. After exposure under a negative, powdered carbon or other permanent pigment was brushed on, and this adhered to the image in proportion to the action of light and consequent degree of stickiness. The picture was then coated with a layer of collodion and soaked in water, when it detached from the glass plate on which it had been formed and was transferred to paper. H. & A.G.

Sensitizing the Tissue. The tissue can be purchased in a range of sizes and colours. Before it is sensitized it will keep in a dry place indefinitely. The tissue can be sensitized by artificial light and will dry in a few hours.

The sensitizing solution is:—

Potassium bichromate	2 ounces	50 grams
Water	40 ounces	1,000 c.cm.
Liquid ammonia ·880	140 minims	7 c.cm.

The best working temperature is 60° F. It should not be above 65° F.

The solution is poured into a dish larger than the tissue to be sensitized and the tissue is immersed in it face down. Any air bells on the front or back of the tissue should be broken. Sensitizing takes three minutes.

At the end of this time the tissue is lifted out and laid coated side down on a sheet of glass, and the surplus liquid is driven out with a flat squeegee. The tissue is then pinned up to dry in a linen cupboard, or any other place which is warm and dark. The tissue does not become sensitive to light until it is almost dry.

When it is dry the tissue is sensitive and must be kept away from the light because the effect of light action once started is continuous. After drying, the tissue should be stored under gentle pressure to keep it flat for use.

Printing. A negative must have greater density and contrast for carbon printing than for bromide enlarging. The thin type of negative that makes a good bromide paper enlargement will not make a satisfactory carbon print. The negative must also be given a "safe edge" so that the print will have a clean white margin. This is done by masking it with lantern slide binding paper.

The print is made by contact. As the surface of the paper is coloured, exposure does not produce a visible image and the correct time has to be found by trial. The usual plan is to print a negative of similar quality side by side with the carbon print on a piece of P.O.P., or self-toning paper. When the test paper shows an image of the right depth the carbon print is fully printed.

Development. During printing, a thin layer of insoluble tissue is formed over the top surface

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

of the tissue. This layer would prevent the action of development, so for development it is necessary to transfer the tissue to another support. If the final print is to show the image the right way round the tissue is transferred to a temporary support at this stage and from this it is transferred again to its permanent support. But if the negative image has already been reversed to allow for the transfer, the tissue is transferred straight to the final support.

Once the tissue has been exposed, the action goes on even in the dark, so the print must be developed very soon after exposure. First the tissue and a sheet of transfer paper are placed together in cold water for about three minutes. The tissue will first curl up in the water and then uncurl. The film surface of the tissue is then brought into contact with the film surface of the transfer paper. Both sheets are picked up together and laid on a sheet of glass with the tissue uppermost. They are then squeegeed firmly into contact so that the solution and any air bubbles are expelled from between the two surfaces. The two are then placed under light pressure between blotting boards for about twenty minutes.

The papers are then soaked in a dish of water at 100° F., tissue uppermost. In a few minutes small quantities of the soluble gelatin begin to emerge from the edges. When this happens, one corner of the tissue is raised and the whole sheet is lifted gently off the transfer paper. The transfer paper should slip by its own weight to the bottom of the dish and if the surfaces are at all difficult to separate, they should be allowed to soak longer, but never forced apart.

The support is now left in the warm water until "development" is complete. As the tissue is very tender at this stage it must not be touched, and it is a good plan to support the paper on a sheet of glass to avoid damaging it. Gentle rocking of the dish to make the water flow across the print helps to speed up development. Development is complete when all the soluble gelatin has gone from the print.

At this stage errors in exposure may be partially compensated for. Over-exposed prints can be reduced by raising the temperature of the water to 120° F. Under-exposed prints should be left to develop face down at a temperature of 90° F.

When the print is developed it is given a rinse in cold water and then placed in a 5 per cent alum solution to harden the gelatin and to discharge the bichromate. It is rinsed again in clean water and then dried.

Double Transfer. In ordinary single transfer carbon printing the image is reversed. It may, however, be printed the right way around by using the double transfer process.

Printing and development is the same as in single transfer printing except that a temporary support takes the place of the single transfer paper. This support may be a sheet of either opal glass or celluloid, previously waxed and polished.

The exposed tissue is transferred to this support, stripped, and developed in the usual way (see single transfer above). It is then dried, after which it is soaked in tepid water with the final support; the two are then squeegeed together and dried. After drying, the print may be stripped without difficulty.

The carbon process can also be used for making colour prints, although carbro is now the more common method.

Wet Carbon Process. When a carbon print of fair quality is needed quickly, the wet carbon process can be used. This is practically identical to the normal process except that the sensitized pigment paper is not dried before exposure.

A sheet of thin celluloid ·003 in. thick is first waxed and polished. The pigment paper is then sensitized in the normal way and then, while still wet, squeegeed into contact with the waxed celluloid. This sandwich is then placed in a printing frame (with the negative against the celluloid) and exposed.

After exposure, development of the sandwich is carried out in hot water as usual. When dry, the image on the celluloid is then transferred to a final support in the same way as in the double transfer process. R.M.F.

CARBON TETRACHLORIDE. Solvent for removing grease and finger marks from negatives; it is non-inflammable.

Formula and molecular weight: CCl_4; 154.

Characteristics: Colourless liquid with fairly pleasant smell. The vapour is toxic.

Solubility: Does not mix with water.

CARBRO COLOUR PRINTS

Carbro is the oldest printing process in general use to-day and many people still consider that the quality of a really good carbro colour print cannot be quite equalled by any other process. If this is true, it is partly because the three colour images which go to make up the print are in relief and give depth and sparkle to the shadows. Other advantages are that it is possible to correct the register even if the separation negatives are slightly different in size: the process takes up very little working space and it is never necessary to have more than two dishes in use at one time.

The cost of a first print is rather less than for dye transfer, but the cost of duplications is greater; the working time taken to make it is at least 2½ hours.

Carbro colour print materials are the same as for single colour carbro except that pigment papers of three colours are used and three

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

TRICHROME CARBRO PROCEDURE. 1. Making separation negatives by exposure through red, green, and blue filters. 2. Processing. 3. Making bromide prints from the separation negatives. 4. Sensitizing cyan, magenta, and yellow tissues. 5 Squeegeeing into contact with the bromide print. 6. Squeegeeing tanned tissue on to temporary support. 7. Developing the reliefs in hot water, followed by chilling, drying, and re-soaking. 8. Registration and transfer. 9. Final transfer.

transparent plastic supports and a paper temporary support are needed.

The starting point for the process is a good set of separation negatives which may be made either from a transparency or direct from the subject. The actual process of making the print divides itself into four stages.

(1) A set of three bromide prints is made from the separation negatives.

(2) From the bromide prints a set of three colour pigment reliefs is prepared by the standard carbro method.

(3) The three colour reliefs are superimposed in register on a temporary support.

(4) The three-colour image is transferred to its final support.

The Bromide Prints. The first step is to make three bromide prints, or enlargements, one from each separation negative. Non-super-coated paper should be used as this helps to get even chemical action between the bromide and sensitized pigment paper. The requirements for the bromide prints are that they should be:

(1) In balance, this means that any part of the subject which is white or grey should print with the same density in all three bromides. Some slight variations may have to be made to suit different batches of pigment paper.

(2) Of sufficient density in the lightest part of the print just to affect the carbro pigment.

(3) Of correct contrast for the pigment sensitizer in use.

The first requirement is a problem common to all separate colour printing processes. The most reliable way of finding the relative exposure needed to balance the prints is by trial and error with a hard grade of bromide paper. A good densitometer can save much of the work, but the measured density differences between the separation negatives will usually have to be multiplied by a factor of between 1 and 1·5 to allow for the Callier effect of the enlarger, before converting to opacities.

The density of the highlight and the contrast of the bromides is largely a question of experience and of suiting the particular pigment sensitizer in use.

If the separation negatives are of different contrast it will be found impossible to match the colourless parts of the subject both in the highlights and shadows. Adjustments for this can be made by using different grades of paper or by altering the composition of the bromide developer. However, it is usually safer to intensify one or more negatives or to vary the composition of the pigment sensitizer as between the three colour images.

The Colour Reliefs. The next stage is that of making the colour reliefs. This depends on the principle that gelatin sensitized with potassium bichromate can be made insoluble either by the action of light or, in the case of carbro, by the chromium salts liberated when a silver

bromide image is bleached. Specially prepared pigment papers are supplied in three colours: cyan (blue green), magenta, and yellow. They are made by adding colouring matter to gelatin and coating it on to paper.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The pigment paper is first sensitized in a solution containing potassium bichromate and other chemicals and immediately brought into contact with the bromide print.

There are a great number of published formulae for pigment sensitizing baths. They fall into two main groups: those employing a single bath and those calling for two separate solutions.

The two bath method is sometimes recommended for those starting the process, because contrast control is simple and depends on the time of immersion in the second bath and because the manual dexterity required in bringing the bromides and tissue into contact need not be so great. The time of immersion in the second bath is, however, critical and the total time in the solution including the time taken to bring the pigment paper and bromide into contact varies from 20 to 45 seconds.

The single bath formula is in many ways more straightforward and is particularly suited to prints of whole plate size or larger. Whichever sensitizer is adopted, it is most important to keep to one formula and to find out exactly the type of bromide print which is suited to it. Nearly all published formulae can give first-class results and it is a great mistake to keep on changing formulae.

The single bath sensitizer has the characteristic that the bleaching action starts immediately the pigment paper and bromide touch. This means that the two must be brought into firm contact quickly. A simple way of doing this is to take two sheets of celluloid and to hinge them together at one end. The bromide and the pigment paper are then placed facing each other on the two sides. They can thus be held apart until the instant when contact is made between them. They are pressed together either by passing them through a mangle or by rolling with a heavy roller squeegee.

After allowing about a quarter of an hour for the chemical action between the bromide and pigment paper to take place the two are stripped apart and the pigment paper is squeegeed face downwards on to a transparent plastic support and left for 10 to 20 minutes. The type of plastic support used is rather important because the surface must be able to hold the relief image during development and also allow it to transfer later on to the support paper. In the old days celluloid was used but this needed waxing to lessen the adhesion and success depended on striking a balance between too much or too little waxing. The wax also had to be removed from the surface of the images after transfer as otherwise the next image would not adhere. Nowadays there are two or three types of plastic obtainable with the right kind of surface and which do not require any treatment.

The Temporary Support. After drying, the reliefs are transferred in turn to a temporary paper support starting with the cyan image. This, on its transparent plastic support, is brought into contact with the paper support under water. After removing the sandwich from the water the two are squeegeed together firmly and allowed to dry. The paper support with the pigment image adhering to it is then stripped off the transparent support. The magenta and yellow images are then registered in turn and transferred on top of the cyan image.

This is done in each case after removing the sandwich from the water by laying it down with the transparent support uppermost and moving the two sides in relation to each other before squeegeeing.

It is possible to obtain register between the three-colour images even if the separation negatives are not of exactly equal size. This is because the temporary paper support can be slightly stretched in relation to the plastic support of the relief. Errors in registration of up to $\frac{1}{8}$ in. on a 10 × 12 ins. print can also be corrected by bending the transparent support inwards or outwards and fixing it in this position during the time the image is being transferred.

The Final Support. After the three images have been combined it is usual to transfer the composite image to a final support. This is not absolutely essential, but the temporary paper support is designed to assist the transfer of the pigment images; also, since the finished print must have the cyan image on top, a direct transfer to the final support would mean registering the magenta on to the relatively pale yellow image, which is generally a difficult operation.

The transfer is made by bringing the temporary and final support into contact under water, squeegeeing them together, and allowing them to dry down. The sandwich is then immersed in hot water, the backing paper of the temporary support is removed and the print is hung up to dry.

With carbro it is most important to have a good working time table so that the various operations which have to be carried out for each of the three colour images can be dovetailed into one another and so that each image receives the same treatment at each stage of the process.

There are several interesting variations on the process and the colour images can be transferred to almost any surface previously coated with gelatin.

It is sometimes said that carbro is a tricky process and it is true that it does sometimes develop faults which are difficult to locate. It is quite common to find that two workers apparently using the same technique do not

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

obtain equally successful results. The golden rule is to decide on the detailed technique to be followed and never change more than one variable at a time. Once the mechanics of bringing the bromide paper and pigment paper into contact and of making the various transfers have been mastered the process becomes straightforward and enjoyable.

H.

CARBRO PROCESS. In these days many photographers who want carbon prints usually make them by the carbro process. In this case the print is made from a bromide contact print or enlargment so there is no need for exposure by daylight and no limit to the size of the picture that can be made from the negative. As the negative can be reversed in the enlarger there is no need for double transferring to make the print appear the right way around.

The carbro process has all the advantages of the carbon process: choice of colour, permanence of the finished print, image quality.

The process was worked out by Thomas Manly about 1905. It was then called Ozotype. Manly first sensitized and made his prints upon the final support. Later he found that the silver image of a bromide print could be made to affect carbon tissue and the result was the Ovobrome process which after improvement became the carbro process as it is today.

The Bromide Print. The basis of carbro is a bromide print that has been normally exposed, developed to finality, fixed, washed, and dried. Only a good quality bromide print will give a good carbro. The print must have a white margin to act as a "safe edge" to avoid frilling.

For best results, the bromide print should be made on non-supercoated paper. Normal bromide papers have a supercoating over the emulsion to protect it from abrasion marks; this supercoating may cause chalky highlights if the print is used for carbro. For this reason, bromide papers are made specially for carbro work without the supercoating.

The bromide print should ideally be slightly soft and of very full density to obtain a good quality carbro print from it. It should also be thoroughly washed and perfectly free from surface stains or deposits.

Two-Bath Sensitizing. The following solutions are needed for the carbro process:—

Stock solution A.

Potassium bichromate	2 ounces	50 grams
Potassium ferricyanide	2 ounces	50 grams
Potassium bromide	2 ounces	50 grams
Water	40 ounces	1,000 c.cm.

One part of stock solution A is diluted with twice its bulk of water. This bath may be used repeatedly if filtered after use.

Stock solution B.

Acetic acid (glacial)	200 minims	10 c.cm.
Hydrochloric acid (pure)	200 minims	10 c.cm.
Formalin (40 per cent commercial)	9 ounces	220 c.cm.
Water	300 minims	15 c.cm.

For use 1 part of the stock solution is added to 32 parts of water. This should be used once only.

The bromide print is soaked in cold water for ten minutes. A piece of carbro tissue, ¼ to 1 in. larger than the print, is sensitized by soaking it for 3 minutes in the diluted A solution. Care must be taken to brush away any air bells clinging to the front or back of the tissue. The dish should be rocked gently. Sensitizing takes 3 minutes. Just before the sensitizing time has elapsed the print is taken from the water and laid face upwards on a sheet of glass.

The tissue is taken from the A bath, allowed to drain and then placed in the diluted B solution. The time in this bath varies from 15 to 25 seconds according to the brilliancy required in the final print. The longer the period of immersion the softer the print.

The tissue is next taken from the second bath and laid face down on the bromide print, starting from one side and lowering the tissue into place to expel the air and prevent air pockets from forming. The tissue is then pressed firmly into contact with the print with a flat squeegee. Chemical action begins almost at once, so any movement between the tissue and the print must be avoided or it may cause a double image.

The print and tissue are then lifted from the glass and left for about twenty minutes between several sheets of greaseproof paper under light pressure.

During this time a piece of transfer paper is put to soak in water. Ordinary paper should have 10 minutes; thick paper rather longer. After soaking, the transfer paper is laid upon a sheet of glass ready for the carbon tissue.

The bromide print and the tissue are now carefully separated by lifting one corner of the print and pulling the two apart. The bromide print, which will be found to have bleached, is put into water to be redeveloped later, and the tissue is placed, coated side down on the transfer paper, and squeegeed into contact. The two are put under light pressure between sheets of paper for twenty to fifty minutes.

Hot Water Development. When the pigment paper and transfer paper have been in contact for the correct time, the two still in contact are placed in a dish of water at a temperature of 95° F. to 100° F. After a short time the pigmented gelatin will be seen oozing from between the tissue and the paper. The two are then separated by pulling them gently apart

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

under water. If they do not part freely they should be left a little longer. After the two are separated it will be found that the pigmented gelatin has been transferred to the transfer paper. Development now proceeds as in the carbon process until all the free pigment dissolves away and leaves the print behind. The dish may be rocked, or water may be poured over the print to assist development. This must be done carefully because the image is very tender at this stage. For the same reason the surface should not be rubbed or fingered.

When development is complete the print is placed in a 3 per cent solution of alum to remove the yellow bichromate tint from the highlights. It is then washed for five minutes in several changes of water and pinned up to dry.

The bromide print may be redeveloped in any non-staining developer and either kept as a bromide print or used to make more carbros. (It is unwise to try to make more than five or six.) The effect of repeated bleaching is to intensify, and many bromides are in consequence better after being used for making carbros. For the same reason subsequent carbros are often better than the first.

By an extension of the carbro process, very satisfactory colour prints can be made. R.M.F.

CARD NEGATIVE. Photographic negative on a card base, which is printed by reflection, as opposed to the conventional transparent negative which is printed by transmission of light.

See also: *Negative card.*

CAREERS IN PHOTOGRAPHY. Photography has much to offer as a career for both men and women. It provides interest, variety and personal satisfaction and can give high rewards for those who possess the ability, personality and, of course, necessary qualifications.

There are many branches providing careers either at a technical level or for professional photographers capable, after acquiring the necessary experience, of either running their own practices or taking control of photographic sections in industrial concerns, hospitals or research laboratories.

The best method of training to become a professional photographer is to attend a 2–3-year training course at a recognized school of photography in a technical college or college of art, studying for the Intermediate and Final Examinations of the Institute of Incorporated Photographers. At least one school of photography (at the Regent Street Polytechnic, London), conducts a further 3-year Diploma course.

The student must first pass at least five subjects (including English Language or Literature) in the G.C.E. at "O" level and some photographic schools require passes in "A" level subjects. It is possible to take up an appointment after passing the I.I.P. Intermediate Examination and to study at evening class for the Final.

In the U.S.A., certain colleges run degree courses in photography.

Portraiture. Portraiture is a branch of photography demanding determination, a pleasant personality, a love of people and strong artistic traits.

There is scope for portrait photographers of outstanding ability and, although not all can hope to reach the top, the person embarking upon portraiture as a career will have a varied and exciting life with opportunities to photograph and talk to many people of interest.

The ideal basis of this career is the training received at a photographic school, followed by entry into a studio as an assistant. It is also possible to enter a studio as a pupil without prior training, studying for the relevant qualifications at evening classes. It is essential, however, that the employer be a bona fide professional photographer of standing.

Advertising Photography. The advertising photographer is an illustrator so that, in addition to his knowledge of photography, he should know the art of pictorial composition. He should also have an inexhaustible interest in life.

A candidate must satisfy himself that in addition to his technical knowledge, he has a marked artistic potential; many photographers prefer an assistant to have had training in a recognized art school as well as the technical training received at a photographic school.

The assistant will probably remain on this level on a rising salary for four or five years.

Press Photography. There is more hard work than glamour in this demanding branch of photography.

Speed of working is important and the press photographer rarely has a second chance to get a particular picture, and little opportunity to size up the subject or wait for better conditions.

Entry to the position of press photographer on the staff of a newspaper is normally through employment as an assistant and photo-printer in the newspaper darkroom. In all but the Fleet Street newspapers and the London Agencies training is, by agreement within the newspaper industry, in the hands of the National Council for the Training of Journalists. Junior press photographers, after a probationary period of six months, are indentured for a three-year period.

To obtain the Council's certificate of proficiency, the I.I.P. Intermediate Examination should be passed (this is a necessity to proceed to the Diploma level), and the I.I.P. Final Examination is a prerequisite to the Council's Diploma. The salaries, negotiated by the National Union of Journalists, vary according to the type of newspaper and town.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Industrial Photography. The activities of the industrial photographer vary as widely as industry itself, so the industrial photographer must be versatile. He may have to produce photographs appropriate for report illustration, for brochure, for advertisement or exhibition stand, and should be able to undertake portraiture, press and scientific photography, document copying and cinematography, according to the specific needs of his firm.

In the lighter industries, there are growing opportunities for girls and already several such departments have staff which is entirely female.

The potential industrial photographer may find that, where possible, experience as a trainee in an independent commercial studio, coupled with part-time day release classes at a school of photography or technical college, offers special advantages.

The prospects of reaching executive positions commanding high salaries are good and the recognition of the value and standing of applied photography steadily increases.

Medical Photography. Medical Photography covers the fields of research, teaching, clinical application and record work. The majority of teaching hospitals, medical institutes and other institutions engaged in specialized work have photographic departments of varying size staffed by men and women. The work demands, apart from photographic qualifications, a flair for scientific work, a sympathy for the ideals which lie behind the treatment of the sick person, and a keen interest in the modern treatment of disease.

The I.I.P. Intermediate Examination is a basic qualification, followed by specialized training in a hospital photographic department or as a student at the London School of Medical Photography, St. Bartholomew's Hospital, London, E.C.1, leading to the Final Examination.

The salaries of medical photographers within the National Health Service are governed by the Whitley Council.

Cinematography. Cinematography, apart from being an entertainment medium, covers the fields of education, instruction, advertising and research. Many large organizations maintain film units to produce technical and prestige films, whilst the smaller film units in particular, require staff proficient in several aspects of production.

Training in the United Kingdom can be obtained at the Polytechnic School of Cinematography, The Polytechnic, Regent Street, London, and in other recognized photographic schools, although facilities generally are limited.

Other Employment. There are various types of employment in photographic establishments apart from the actual taking of photographs. It is usually necessary, and certainly desirable, to obtain experience in processing and printing at the beginning of a career in photography. Indeed, these and other occupations in photographic establishments provide satisfying careers in themselves.

The people who develop or process the negatives also do an important job, because unsatisfactory work at this stage may be irreparable.

Photographic printing permits a very high degree of skill. The demand for skilled printers greatly exceeds the supply, while there is generally a small surplus of camera operators.

The retoucher requires some artistic ability and again need not have photographic training, although a good general knowledge of photography is helpful. The work calls for some ability with pen and brush, a sense of judgment and a keen appreciation of light and shade, form and texture. Retouchers are mainly employed in portrait studios and in commercial and advertising work; the latter demanding the higher standard of artistic ability. There is always a shortage of good retouchers, particularly in commercial photography. Most retouchers are women.

Finishing again is usually done by women. The finisher is responsible for the final appearance of the print, spotting to remove small blemishes, and mounting. The ideal combination is a retoucher-finisher who has the skill necessary to carry out the complicated corrections so often called for in commercial subjects.

In work for reproduction where very highly-skilled craftsmanship is called for, it is usually carried out by a process finisher who must be a capable commercial artist.

The receptionist is an important member of the portrait studio staff, and in many instances the success of the business largely depends upon her skill. She does not require a photographic training, but needs to be interested in people and photography and to be able to inspire confidence; she must also be a good saleswoman and may be required to do clerical work and accounts.

Examinations. Details of the examinations mentioned in this article, including syllabuses, sessions, entry fees, exemptions, etc., may be obtained on application to the Education Officer at the Institute of Incorporated Photographers.

Training in the subjects contained in the examination syllabus can be obtained by attending photographic schools on a full or part-time basis and advice on the availability of such schools may be obtained from the Institute. With effect from the 1st September, 1965, no student is permitted to sit the Intermediate and Final Examinations of the Institute unless he or she has satisfied the educational standards required (e.g. G.C.E. "O" level passes, or equivalent, in 5 subjects, including English Language or Literature), and is a Registered Student of the Institute. J.L.A.H.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CAREY-LEA, MATTHEW, 1823–97. American chemist. Carried out many photo-chemical researches: advised the use of green glass for safelights in darkrooms and for the better preservation of sight. Introduced the mordant dye pictures (1865). Investigated the latent image and the development process, especially ferrous oxalate developers (1877–80).

CARJAT, ETIENNE, 1828–1906. French caricaturist, writer and editor of *Le Boulevard* 1862–3, he also photographed celebrities 1855–*c.* 1875. His portraits are often livelier than Nadar's and have been undeservedly overshadowed by the latter's great reputation.

CARROLL, LEWIS (the Rev. Charles Lutwidge Dodgson), 1832–98. English author of *Alice's Adventures in Wonderland* and amateur photographer 1856–80. His favourite subjects were little girls, and Helmut Gernsheim's rediscovery of Carroll's photographic work proves him to have been the best photographer of children in the nineteenth century. He also photographed celebrities. Biography: *Lewis Carroll—Photographer* by Helmut Gernsheim (London, 1949).

CARTE-DE-VISITE. A photograph, usually a full-length portrait, on a mount the size of a visiting card. The carte-de-visite album containing portraits of family, friends, royalty and celebrities was a typical feature of the mid-Victorian drawing-room. The first photographer to make cartes was Dodero of Marseilles in 1851, but it was André Adolphe Disdéri of Paris who popularized them. In November, 1854 Disdéri patented a method of cheapening the production of portraits by taking ten (in fact usually eight) on one plate and cutting up the resulting print. The fashion for this format dates from May, 1859 when Napoleon III had a carte portrait taken by Disdéri. During the 1860s, at the height of the craze, cartes of celebrities were sold to the public in hundreds of thousands and fortunes were made by leading photographers. The price of a carte varied from 1s. to 1s. 6d.

CARTOON. Motion picture film produced by successively photographing series of drawings which reproduce the movement phases of cartoon characters at a realistic or imaginary rate. The first cartoon films are almost as old as cinematography itself. Today the animated cartoon is—apart from its rôle in entertainment—an important means of advertising in the cinema and on television.

See also: *Animation.*

CARTRIDGE. Term applied to a type of packing for 35 mm. film in measured lengths; nowadays generally known as a cassette.

CASE. Cameras and their accessories are fragile pieces of equipment needing protection when they are being carried about.

Block Form Cases. The old-fashioned camera case is constructed like a box with a flap covering the top and held down by press studs or a tongue and buckle. When designed to hold a folding camera, it has rounded corners and is fitted with a carrying strap which allows it to be carried slung over the shoulder. Block form cases for rigid cameras, e.g., box and reflex cameras, and for heavier types, e.g., technical and view, have a handle on top of the case and the lid is firmly held down with straps. Such cases usually have a compartment for half a dozen plate holders, alternative lenses and focusing cloth.

Ever-Ready Cases. It is usual nowadays for camera cases—and sometimes exposure meter cases—to be designed so that they can be left in position without affecting the use of the instrument. A case of this type is known as an every-ready case. The camera is generally held in its ever-ready case by a screw which fits the tripod bush. As a rule, the top and front of the case are formed by a single flap of leather that folds down uncovering the self-erecting front of the camera, or the lens and the range finder, viewfinder, etc., allowing them to be operated normally while in the case.

The flap of an ever-ready case should hang clear of the field of the lens when it is open. In some cases the material is stiff and tends to spring back and obscure the view of the lens although the intrusion is not apparent in the viewfinder. With the type of case in which the flap folds down behind the camera instead of hanging in front, the trouble cannot occur.

The screw which holds the camera in the case may itself be drilled and threaded to take the tripod screw. This enables the camera to be used on a tripod without taking it out of the case.

Water-tight Cases. One or two manufacturers produce special camera cases which close hermetically and so seal off the camera against moisture, dust or other outside influences. The cases are designed to be buoyant so that the camera and its case float even when dropped into the water. Often a cartridge of silica gel or similar water absorbing substance keeps the interior fully dry. These cases must not be confused with underwater camera cases, which permit photography under water.

Hold-all Cases. The miniature camera and its range of accessories cannot be carried about conveniently in separate cases. Specially designed hold-all cases are available to take the whole outfit. They are made either in the form of an attache case with fitted compartments or arranged as a shoulder bag. For outdoor photography it is more convenient to have a bag with a shoulder sling.

Hold-alls are made either for general use with any equipment, or tailor-made for specific makes. Some also have adjustable

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

compartments, formed by means of press studs, so that the inside can be arranged to suit the combination of equipment in use.

Lens cases. Individual lens cases are useful for cameras equipped with a range of interchangeable lenses. The commonest type of lens case is a leather tube, closed at one end with a removable cap at the other. The case is lined with velvet or foam plastic and usually has two outside loops for threading on to the camera case shoulder strap. This type of case is practical and robust but the movement of the lens inside tends to work up dust and fluff which inevitably transfers itself to the glass surfaces.

Transparent plastic holders are cleaner and better-looking but they are bulkier, and apt to be more fragile than the lined leather type. In addition they are not suitable for fitting to the camera strap and have to be mounted in the hold-all case. Their greatest attraction is to the camera dealer since they provide dust and finger-proof display cases. This type of case consists of a circular base with a Perspex dome attached over it by a bayonet or screw fitting. The base carries a lens mount identical with that of the camera. The lens is attached to this mount and then covered with the Perspex dome.

CASSETTE. Light-trapped metal or plastic container for a length of film to enable it to be loaded into a camera in full light. It is an alternative to spooling the film with an opaque backing paper, and is used mainly for perforated 16, 35 and 70 mm. film.

In the standard type the bare film is wound on a spool in darkness or safe illumination, and then placed in a cylindrical cover with the end of the film projecting from a light-trapped slit in the side. The cassette is placed in the loading chamber of the camera and 4 ins. or so of the film drawn off to attach the end to the camera's take-up spool. On closing the camera this fogged end has to be wound off by advancing the film two or three frames.

After exposure the film usually has to be rewound into the cassette before it can be removed from the camera. The cassette spool is therefore keyed to engage with the rewinding knob fitted to the camera. The other end of the spool has a short extension which projects from the cover so that it may be turned by hand if required. However, a few cameras are designed to use a take-up cassette to obviate rewinding.

STANDARD CASSETTE. Left: *Complete cassette.* Centre: *Shell with velvet-lined slit, and lid.* Right: *Spool.*

THE RAPID SYSTEM. This uses a feed cassette and a take-up cassette in the camera. On inserting the feed cassette with its protruding film, the transport sprocket inside the camera automatically pushes the film into the take-up cassette. A, *take-up cassette.* B, *feed cassette.* C, *film.* D, *transport sprocket.* Bottom: *Inside the cassette the film is wound up between a loose core* E *and a spring* F.

Film Manufacturers' Cassettes. 35 mm. film is supplied in cassettes ready for loading into the camera. These are of simple construction, the slit or "mouth" of the cassette having a light trap of velvet or plush. This material is sometimes carried right round the interior of the cover, the two ends projecting from the mouth. They are not intended to be used again, but usually they may be loaded two or three times if care is taken to keep the plush clear of grit particles, which will otherwise scratch the film. The mouths of metal cassettes can be opened, after removing the end caps, to brush the plush.

The normal 35 mm. cassette holds enough film for 36 exposures 24 × 36 mm., and is suitable for most 35 mm. cameras taking other picture formats (18 × 24 mm., 24 × 24 mm., etc.).

One type of cassette holds single-perforated 35 mm. film in 12- or 20-exposure lengths for 26 × 26 mm. pictures and is designed for specific cameras only. Here the film is wound up together with a backing paper. This cassette is not reloadable and the film can only be removed by breaking up the cassette. The film is pre-threaded with a feed and a take-up chamber built into the cassette, permitting instant loading into the camera without separate threading. The rapid system also uses a quick-loading cassette, but holding 12-exposure lengths of standard 35 mm. film.

Subminiature 16 mm. film is supplied in cassettes also for loading into the camera, and of similar construction to standard 35 mm. cassettes. There are several types of 16 mm. cassette: single cassettes involve rewinding of the film when the whole film is exposed; double

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

cassettes (usually with two chambers joined by a connecting piece) need no rewinding.

Reloadable Cassettes. These are substantial camera accessories. They are accurately made, usually in brass with a black anodized finish, and may be used only in the make of camera for which they are designed. There are, however, certain universal cassettes that can be used with many 35 mm. cameras for which reloadable cassettes are not otherwise provided.

In addition to being reloadable and more substantial, these cassettes are designed to dispense with the plush light trap; instead of the film being drawn through plush, it leaves the cassette through a wide opening to eliminate the possibility of cassette scratches.

The body consists of two accurately made sleeves, one sliding within the other. In each there is a longitudinal opening. When the spool of film is inserted and the cassette assembled, the inner sleeve is rotated so that the openings are diametrically opposite, and the cassette is therefore light-tight. The sleeves are machined to permit the end of the film to project. When the cassette is loaded into the camera, the mouth is opened automatically on closing the camera by turning the inner sleeve until the two openings coincide—hence the term "self-opening" that is often applied to these cassettes. Alternatively, the film may pass through a light-trapping channel, requiring no opening movement. Similar cassettes are available for 70 mm. film, and are loaded from bulk lengths. Here the cassette again has a light-trapped slit, and is essentially a scaled-up version of the standard 35 mm. cassette.

Loading Refills. 35 mm. film refills for reloadable cassettes are normally provided in lengths for 36 exposures 24 × 36 mm. The standard over-all length is 1·6 metres (5 ft. 3 in.) which allows for about 9 ins. of free film to provide a long leading end and a shorter spool end. The leading end is trimmed to half its width for 4 to 5 ins., which is necessary for the film to lead on to the top sprocket of a number of miniature camera models. The other end is trimmed to a "V" for attachment to the cassette spool.

SELF-OPENING 35 mm CASSETTE. Left: Complete cassette. Centre and Right: Spool, inner shell, outer shell. The cassette is opened inside the camera by turning the inner shell (usually by the camera locking key) so that the slots coincide.

The film is loaded into the cassette in the darkroom. The end is attached to the spool by means of the slot or clip, or by means of adhesive tape, and the film wound on to it by turning the spool with the right hand whilst feeding the film from the left hand, checking the edges with the thumb and forefinger to apply light pressure. Mechanical film winders can speed up this operation.

Refills may also be supplied for daylight loading. The film is ready wound on a spool and is protected by a black paper leader attached to its end. The spool is inserted in the cassette with the paper leader projecting from the light-trapped slit. The leader is then drawn off to bring the end of the film through. Daylight refills are normally available only for 35 mm. cassettes.

Loading Bulk Film. 35 mm. film for still cameras is supplied in untrimmed lengths up to 100 feet

SELF-CONTAINED EASY-LOADING CASSETTE. The whole cassette goes into the camera without any film threading or other manipulation. Inside, the film runs from a feed roll on to a take-up spool but is not re-wound. The cassette must be broken open to extract the film for processing. A, take-up spool shaft to engage film transport in camera. B, perforation aperture for transport control. C, picture opening. D, take-up spool. E, notch for film speed setting in camera. F, feed roll.

FILM LENGTHS FOR VARIOUS NUMBERS OF EXPOSURES

Number of Exposures	Length of film		Number of Exposures	Length of film	
	in.	cm.		in.	cm.
1	10½	27	20	39	99
2	12	30	21	40½	103
3	13½	34	22	42	107
4	15	38	23	43½	110
5	16½	42	24	45	114
6	18	46	25	46½	118

or 30 metres. The required length is cut off in the darkroom, the ends trimmed to shape, and loaded into the cassette. Scissors may be used to trim the film by "feel", or better a metal template may be used and the film shaped by running a knife round its edge. If the film length is cut off to the trimmed shape using the template, a tongue of the correct shape is left on the film stock and will serve for the next loading. This is the most economical method.

Perforated 70 mm. film for still cameras is usually supplied in untrimmed lengths of 100 feet (30 metres) or longer. This is loaded into the cassette in more or less the same way as 35 mm. film, though a leading tongue is not usually required. H.H. (L.A.M.)

CATCHLIGHT. In a portrait, tiny highlight on the eye created by the reflection of a bright light source.

If there are no catchlights in a portrait the eyes tend to look lifeless and the eyeball lacks roundness. If the lighting used for the portrait is such that no natural catch-lights are produced, then the addition of a weak directional light—not sufficiently powerful to affect the general lighting of the portrait—placed not far from the camera-viewpoint, will create these.

It is common practice to add catch-lights by means of retouching and knifing, on either print or negative.

These highlights should not be positioned centrally on the eye, but to one side, and if the lighting used has produced central catch-lights, these should be removed and replaced, by means of retouching, slightly to the side.

CATECHOL. Developing agent; pyrocatechin. Used in tanning developers and has been employed in some fine grain formulae.

CATHODE RAY TUBE TRACES

The cathode ray tube is a modern scientific tool with a wide and ever increasing field of applications (television is the most popular of these).

The tube is an evacuated glass bulb in which a narrow stream of electrons emitted by the cathode is made to pass between pairs of plates. When a voltage is applied to these plates it deflects the stream of electrons from its straight path. This arrangement forms a delicate and weightless recording instrument which will follow very rapid changes in the magnitude of the deflecting voltage. So any physical change (which need not necessarily be electrical) that can be made to modify the deflecting voltage can be reproduced as a visible trace on the end of the tube.

Types of Trace. The movement of the electron beam can be recorded either directly on a photographic plate, or indirectly by photographing a fluorescent screen which glows where the beam strikes it. Since the cathode ray itself leaves no lasting trace, scientists naturally want to be able to make permanent photographic records of any traces that interest them. The photographic method used depends on the type of trace to be recorded. There are four principal types: traces which record the same change repeated at regular intervals (repetitive); traces of single transient events—i.e., events that happen once only; traces that are continuously changing without ever repeating themselves (slow, non-cyclic); and traces that repeat at regular time intervals but may be different each time (cyclic, non-repetitive).

Methods. Transient and repetitive traces may be photographed on a stationary film or plate. A transient trace occurs once only, so it is more difficult to photograph than the trace of a regular cyclic event to which the plate can be left exposed until it has built up an image of the required density.

Non-repetitive and non-cyclic events may be photographed on a film wrapped around a revolving drum and moving at right angles to the path of the trace. In this case a time base may be added to the photograph by applying a regular voltage pulse to a second pair of control plates set across the beam.

Slowly changing cyclic events may also be recorded by a cinematograph camera so long as the time interval during which the shutter remains open is long enough to include more than two complete cycles.

Photographic records of traces obtained by such methods have two great advantages; they are permanent, and they can be enlarged for more detailed study. The recorded traces can also be compared directly and stored for reference. When traces are over so quickly that the eye cannot see them it is possible to photograph them automatically. Even when the phenomena occur at irregular intervals there

CATHODE RAY TUBE. A, control grid; B, electron gun; C, vertical time base; D, horizontal time base; E, fluorescent screen coated on inside of tube; F, deflector plates.

is no need for a constant watch to be kept on the apparatus.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Continuously Evacuated Tubes. When the trace is recorded by allowing the beam to impinge directly on the photographic material, the film or plate is actually put into the tube. Such work calls for a continuously evacuated tube. This is a tube which can be opened up to allow the sensitive material to be inserted, and then hermetically sealed. It is then evacuated by a vacuum pump.

The film or plate inside is kept covered with a metal shutter which can be opened at the time of exposure.

Exposures as short as 10^{-9} seconds can be made with this type of apparatus, but the tubes are bulky and expensive. They also take a long time to reload because the air has to be pumped out again each time the tube is opened to change the sensitive material. Tubes of this type can be made to accommodate both still and drum type cameras.

Permanently Evacuated Tubes. Permanently evacuated and sealed tubes are more generally used than the type just described. With these tubes traces may be recorded by the direct action of the electrons on the photographic material. In this method, the tube is equipped with a window (generally of thin metal foil) which is thick enough to maintain the vacuum but thin enough to let the electrons pass through. Suitable windows are made of aluminium, glass, or Cellon, about 0·001 cm. thick.

The sensitive material is exposed to the rays after they pass through the window so that all the photographic equipment remains outside the tube and at atmospheric pressure.

Fluorescent Screens. Traces can also be photographed by fitting a screen of transparent fluorescent material into the end of the tube. When the electron stream strikes the screen it creates a visible fluorescent image which persists long enough to be photographed. The fluorescent image may be recorded by normal photography, as in mass miniature radiography or by exposing sensitive paper or film in contact with the screen.

With the conventional type of cathode ray tube, prints made by contact are always slightly unsharp because of the thickness of the glass wall of the tube. This leads to a certain degree of diffusion. The grain of the screen also limits the sharpness of the images recorded by normal photography.

Tubes with the front wall in the form of a fibre window give better contact prints. Here an array of short glass fibres at right angles to the tube surface are fused together to form the window. Each fibre acts as a light guide, transmitting the luminous spot of light from the phosphor coating on the inside of the tube to the paper or film on the outside. These light points are perfectly sharp, but the resolution of the image depends on the fibre diameter.

FIBRE WINDOWS. A fibre window can be used with a cathode ray tube to record an electron beam scan direct on a moving film. The beam (dotted) here scans at right angles to the plane of the diagram. A, moving film. B, cathode ray tube envelope with its face plate consisting of a fibre bundle with a fibre axis at right angles to the surface. C, phosphor layer. D, electron beam.

Cathode ray tubes with such fibre windows are widely used in computer print-out devices to record letters and figures on the sensitive material in contact with the tube.

For isolated high-speed transients slow decaying phosphors may be used for the fluorescent layer. The wave form or other image to be recorded there persists sufficiently long to make a developable impression on the photographic emulsion, even though the actual phenomenon causing the trace may have lasted only a microsecond or less.

Contact printing must, of course, be carried out in darkness or by a suitable safelight, but when a camera is used it can be connected to the tube by a light-tight extension.

Cameras for this type of fluorography need fast, coated lenses of the order of *f* 1·9 to *f* 1·0, and the shutter may have to be synchronized with the spot so that the film will not be affected by the afterglow on the screen which may last up to five seconds. The type of film used, whether ortho, or pan, depends upon the colour of the fluorescence. This varies according to the coating material. As a rule development is prolonged to give a high contrast image, and in addition, it is often necessary to intensify the image, especially when dealing with high-speed writing made at anything up to 5,000 km./sec. (one-sixtieth of the speed of light).

Drum cameras are used for recording non-cyclic traces. The film is wound around a drum which is made to rotate at a suitable speed. The drum may be up to 50 cm. diameter and the speed of rotation may reach 6,000 r.p.m. It is enclosed in a light-tight housing with a slit behind which the moving film is exposed. A shutter uncovers the slit at the instant of exposure.

With this type of apparatus, very brief traces can be photographed at film speeds as high as 50 metres per second. For longer traces it is necessary to use a camera in which a length of film is wound off a storage spool and on to a take-up spool after exposure.

The Polaroid Land camera can now be attached to many oscillographs. This permits the production of a permanent record in

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

empty box never fails to inspire them to a bout of hilarious clowning. Here also the table-top technique is the most convenient. Once the subject is confined within the limits of the table-top (and the depth of field of the lens), it is easy to attract its attention in any desired direction by dangling a string or making a sudden noise.

The more convincingly small and helpless a kitten can be made to appear in a photograph, the better. This can be done by including some object in the picture area to contrast with the kitten. Hard, angular box shapes will emphasize its fluffiness, a shopping basket accentuates its relative smallness, and so on. But the animal should never be decorated with bows of ribbon and frills. In all other particulars photographing kittens does not differ from photographing cats. P.J.

CAUSTIC OF LENS. If a simple converging lens is considered as consisting of a series of concentric rings, the focal length of these rings gets progressively shorter as the diameter of the rings increases. So when parallel rays of light fall on the lens, the rays from the edges converge more steeply than those at the centre. This effect is known as spherical aberration.

CAUSTIC CURVE. Rays from the edges of a simple positive lens converge more strongly than central rays. In crossing each other the sets of rays form a brilliant curve of light.

This means that each ray crosses the path of its next outside neighbour. Where the rays cross they produce a point of high intensity. All these points of high intensity lie on a curve called the caustic of the lens.

A curve of this type can be seen on the top of a cup of tea when the sunlight is reflected off the inside of the rim.

CAUSTIC POTASH. Corrosive alkali occasionally used in developers, especially high contrast types.

See also: *Potassium hydroxide.*

CAUSTIC SODA. Poisonous and corrosive alkali. Used in some developers, especially high contrast types.

See also: *Sodium hydroxide.*

CAVES. There are caves in practically every country in the world, formed by actual movement of parts of the earth's crust, by the dissolving action of subterranean water or by the scouring action of waves along the coast. Almost always, the interiors are of interesting and often beautiful conformation, and as such are well worth photographing.

Caves and pot-holes abound in the limestone hills of England and Wales. They lie in four main groups or districts: the north-west border of Yorkshire, the Peak District of Derbyshire, the Mendip Hills in Somerset, and the upper reaches of the Neath and Swansea valleys of South Wales. And they are all easily reached from the principal industrial centres.

The charm of cave photography lies in the novelty of the subject and in the fact that the "scenery" owes nothing to the hand of man, being entirely the result of natural action. Mountain streams boring down through the limestone have carved out a maze of subterranean passages decorated by a surprising variety of stalactite and stalagmite formations. (The stalactites hang from the roof.)

The cave photographer has his own peculiar difficulties, for he must possess endurance to reach his objective and patience in working in often damp and awkward conditions. On the other hand, he has the advantage of having everything under control. Exposure is controlled by lighting, and the subject (apart from flowing water) is static.

Equipment. Photography underground owes a lot to the 35 mm. camera, colour film, and the development of small high-output flash bulbs. This does not rule out the use of larger cameras, but it must depend upon the purpose for which the photograph is intended and whether the conditions will permit a more bulky load.

Apart from the 35 mm. camera's obvious advantage of compactness, a 3·5 cms. wide-angle lens (the most versatile lens underground) can be used at full aperture and still retain sufficient depth of field for most subjects. In large chambers where the foreground is not intrusive, maximum aperture will make the most of your flash. Synchronized flash is not essential with pictorial or record shots, but it can prevent accidental light traces from someone else's light intruding in the picture; it will certainly make more candid action shots practicable.

Lighting. Open flash can be used with flashbulbs, and must be used with flash-powder, which serves admirably in any large chamber which cannot be adequately covered by flash bulbs. As little as a quarter of an ounce of

flash-powder will illuminate a vast chamber at an aperture of f 3·5. Guidance on exposure is given by the manufacturers of both bulbs and flash powder, but it is advisable to assume the worst conditions of those given in the tables unless the subject consists almost entirely of white calcite formations. Whichever flash is used, it is advisable to keep it above ground level to avoid a burnt out foreground.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

All the normal rules of photography apply to the placing of the flash, and the entire lighting is controllable. Flash illumination may be placed within the picture area, provided the light source is shielded by some object or part of the cave, so that it does not shine directly into the lens. Lighting from one side of the camera will always give the more dramatic effect and bring out texture, and a stretch of passage may be illuminated with considerable effect by back lighting from round a corner. Here the critical factor for exposure is the distance of the flash from the subject, which should always be appropriate to the lens aperture in use, whatever the position of the camera.

Electronic flash may be used if available, although there is much to be said for flash bulbs in conditions of high humidity, and where hard knocks are likely, or space is limited. The type of flash must be related to the type of film, especially when colour film is used.

Film. It is difficult to convey a true impression of a cave in monochrome to someone unfamiliar with the subject. Appropriate colours are substituted subconsciously on viewing monochrome photographs of more familiar scenes. This might be said to add to the challenge, and monochrome slides and prints of excellent quality can be produced and are of the greatest value for reproduction purposes, where costs rule out colour. But where the record is most important and transparencies are required for projection, colour film is the answer. There are some beautiful colours, ranging from bright red to the more subtle shades of the surrounding rock, the blue of still pools and running streams, and the wonderful cave paintings of France and Spain which demand the use of colour film. The emphasis must be on the accuracy of the rendering of the colouring.

The make of film is a matter for personal preference and it may be of the daylight type used with blue bulbs or electronic flash, or alternatively an artificial light film used with clear bulbs and the appropriate correction filter. An exceptionally fast film is not essential, unless a small aperture must be used, or full use must be made of the flash bulb's output.

Flash-powder can be used with artificial light film quite satisfactorily, although the colour balance may vary slightly with larger quantities of powder, or when the powder has been kept a long time after mixing.

Flash-powder used with open flash is a simple process of securing the camera on its tripod, judging the subject through the viewfinder by painting it in with the light of a torch, opening the shutter and then igniting the fuse for the flash powder. This will allow the photographer to appear in the photograph since the fuse acts as a delayed action device. Celluloid strips 9 ins. long make excellent fuses, and also illuminate the scene.

A figure in an underground photograph, in an unobtrusive position, helps to indicate scale, and adds interest. Subjects such as calcite cascades, curtains and stalactites have beauty and interest, but may still require something to give scale

Cine. Cinematography offers an even greater challenge. The intense light given in a fraction of a second by a flash bulb, which is adequate for still photography, cannot be maintained continuously whilst the cine camera is operating.

The main problem (away from a public electricity supply) is lighting. Lighting can be provided by battery, pressure lamps and types of portable gas lamps. Of these, the most satisfactory are the highly compact battery units in conjunction with high output lamps designed for low voltages. Output is in any case limited, so it is desirable to use the fastest possible film with acceptable grain for the purpose. Under extremely poor lighting conditions it might be necessary to use less than the normal number of frames per second, in order to give sufficient exposure to each frame.

Precautions. There are very many caves which the photographer can explore without danger if proper precautions are taken. But even the easiest cave can become a dangerous place to be in if you sprain an ankle or suffer any other simple mishap which prevents you moving freely.

So when going caving do not go alone; always carry spare lights—even if only 2–3 candles and water-proofed matches; find out all you can about your proposed objective; see that you are properly equipped; and tell someone responsible of your trip.

B.T. (L.B.C.C.)

See also: *Geology; Mountains.*

C.C. FILTER. Colour correction filter used in colour photography and for control in making colour prints. C.C. filters have a selective colour absorption in one or two of the three main spectrol bands. They exist in a range of densities in the three complementary and the three primary colours (cyan, magenta, yellow; red, blue, green). Their designation frequently indicates both their colour and their density: for example a C.C.20M filter is a magenta colour correcting filter with a density of 0·2 (to green light). C.C. filters can be used to eliminate colour casts, but do not have the absorption characteristics required to change the effective colour temperature of any given type of light.

CELL. Enclosed compartment with transparent or opaque walls containing one or more liquids or solids intended to react with each other chemically under controlled conditions, or to affect light or other energy passing through it. There are accordingly a number of completely different kinds of cell. For photography the following are relevant.

Electric Cell. This is a container with two conducting electrodes of different materials (usually different metals) dipping into a suitable solution. When the electrodes are connected together externally, a current flows from one to the other. At the same time the solution (the electrolyte) reacts with the electrodes. This is the reaction which provides the electric energy. So-called dry cells contain the electrolyte in the form of a jelly or absorbed in a suitable material. The construction of a cell may be quite complex to improve the efficiency of the current generation. A number of connected cells form a battery.

Filter Cells. A small transparent glass or plastic container, filled with a dye solution or a solution of suitable coloured salts can be used as a filter in photography and photomicrography. Since dyes and coloured chemicals in solution have accurately known spectral characteristics, it is in this way possible to prepare filters of precisely standardized specification.

Microscope Cell. Very small transparent containers are used to hold liquids carrying small organisms for investigation under the microscope. In its simplest form such a microscope cell may consist of nothing more than a glass slide with a recess to take the liquid, and a thin cover glass.

Photo-Electric Cell. Certain metal layers in contact with other metals are able to generate electricity when light falls on them, or may vary in their conductivity of an electric current when exposed to light. Such assemblies are used as light-sensitive cells.

See also: *Batteries; Filters; Photo-electric cell; Photomicrography.*

CELLULOID. Transparent and flexible solid, principally pyroxylene with some naptha, amyl acetate, oil and camphor. Invented in 1861 and much used as a base for photographic films in the 1880s.

See also: *Supports for emulsions.*

CELLULOSE. Main basis of the acetate and nitrate bases used in film manufacture. Cotton wool is pure cellulose.

CELSIUS SCALE. Continental temperature scale having 0° as freezing point and 100° as boiling point. Commonly known in England as Centigrade scale.

CEMENT. Adhesive, usually consisting of solvent-based or thermo-setting or thermoplastic synthetic resin, used for a variety of joints in photographic apparatus. Special optical cements are employed for joining lens components, prisms and other glass elements.

See also: *Adhesive.*

CENTI-. Prefix implying a hundredth part of. Principally used in metric system—e.g., centimetre.

See also: *Weights and measures.*

CENTIGRADE SCALE. Internationally termed the Celsius scale. Thermometrical scale on which zero represents the freezing point of water (and melting point of ice) and 100 degrees represents the boiling point of water at sea level. The Centigrade scale is now replacing the Fahrenheit scale in this country, and it is usual to include after a Fahrenheit reading its Centigrade equivalent.

See also: *Thermometer; Weights and measures.*

CENTRE OF INTEREST. That part of the picture to which the eye of the observer automatically travels; it is decided by the arrangement and lighting of the subject. Normally there should be only a single centre of interest; if there are more, the result generally tends to confuse the eye.

See also: *Composition.*

CERAMICS. The two biggest problems to be overcome when photographing ceramics are reflections and distortion.

Eliminating Reflections. Nearly all reflections can be eliminated by use of a suitable lighting technique. Lighting is normally from a single source (preferably a spotlight) to give crispness and modelling to the subject. Shadows are softened by a white reflector, which may be lighted up by another spotlight if the contrast of the subject is too great. The subject is lighted from the side or between side and back, roughly between 80° and 180° from the camera. Once the photographer has found a position giving satisfactory modelling, he adjusts the spotlight vertically until any highlights disappear. With tall objects such as jugs or vases this will occur when the spotlight is in a high position. With flat objects such as plates or shallow bowls, where highlights are not so troublesome, the spotlight is placed much lower to give effective modelling. This method of lighting gets rid of all reflections from flat objects and practically all from taller ones.

Dealing with Distortion. The aim of this type of photograph is to give as accurate a representation of the subject as possible. Distortion, from whatever cause, cannot be tolerated. There are two principal causes of distortion: viewpoint too low and tilting the camera.

Too low a viewpoint when photographing on

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

LIGHTING POTTERY. A spotlight from near the side of the subject gives crispness and modelling. It should be at a sufficiently high angle to make catchlights disappear. A white reflector (not shown) is usually necessary to light the shadows, while another spot can be used for background effects.

to a table-top causes round flat objects to appear oval, a defect intensely disliked by pottery manufacturers. So, for subjects like plates or dishes, a very high viewpoint is used so that the camera is looking almost vertically down. Where there are both flat and taller objects combined, as when photographing a tea set, the problem is best solved by standing up the plates behind the taller objects such as cups and jugs. This arrangement gives a pleasing and undistorted grouping. In this case, of course, the viewpoint is lowered so that the camera angle is between 0° and 20° above the horizontal.

Tilting the camera so that the back is no longer vertical—e.g., when photographing down on to the subject—causes perpendicular lines to run inwards to the bottom so that objects on the edges of the photograph appear to be falling over outwards. This distortion is completely rectified by swinging the back of the camera into a vertical position.

A further form of distortion arises with wide-angle lenses when the angle of view appreciably exceeds 60°. Solid objects near the edges of the field appear elongated in a direction away from the lens axis; e.g., spherical shapes become oval.

The Background. Backgrounds for ceramics are always kept fairly plain so that they do not conflict with the pattern or shape of the subject. Wood grained wallpapers offer an excellent variety of background varying from the light tone of pine to a dark walnut if required, and textured paper or fabric is also used with pleasing effect as background material.

As a rule when pottery is photographed from a low viewpoint, the subject is kept well in front of the background which then remains slightly out of focus. To increase the feeling of depth in the photograph it is common practice to shine a spotlight on the background on the shadow side of the subject. This means that the dark side of the subject stands out strongly against the lighted background.

The Camera. The photographing of ceramics is best done with a professional bellows type of camera with full camera movements to allow for the correction of distortion and the achievement of the maximum depth of field. A stop of *f* 45 or *f* 64 is normally used to ensure overall sharpness.

It is customary to use a plate of fairly soft gradation, and to take care to produce the required balance of light and shade in the image on the ground-glass screen. Under these circumstances, normal development in a M.Q. developer gives a completely satisfactory negative.

Photographs of pottery or china are usually considered to look their best on a glossy printing paper. D.L.H.

See also: *Antiques; Close-ups; Glassware; Lighting the subject; Silverware.*

CHANGING BAG. Bag made of opaque fabric which allows sensitized materials to be handled and loaded into the camera in daylight. There are sleeves at each side of the bag through which the hands and the lower part of the arm are inserted. There is elastic in the open ends of the sleeves to stop light from leaking past.

The camera and film or box of plates is first pushed through one of the sleeves—or through a separate light-trapped flap—and then the sleeves are pulled well over the arms. From that point, the loading or unloading can proceed without any risk of accidentally exposing the film or plate.

Changing bags originally had a window of ruby fabric or celluloid which admitted safelight into the bag and a pair of eye-holes through which the user could see as well as feel what was going on. And a box often took the place of the body of the bag, so that it was

CHANGING BAG. The bag usually consists of a light-proof black fabric with sleeves bound by elastic at the ends. A zip fastener serves for placing the equipment in the bag.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

actually possible to develop plates by inspection. These elaborations could only be used with slow, "ordinary" plates which could stand a fair amount of red light. The greater sensitivity of orthochromatic materials and the increased use of panchromatic materials has put this sort of equipment out of date.

Nowadays changing bags are used principally for loading plates into plate holders and films into daylight processing tanks. They are also used by dealers when a customer brings in a camera with a jammed film.

CHARACTERISTIC CURVE

This shows how light acts on a photographic material and produces a density on development. The image formed in the camera consists of patches of light of varying intensity which are all allowed to act on the photographic material for a constant length of time. So the various exposures which make up the image are exposures of constant time and varying intensity. All these different exposures reproduce as a range of densities on development. In a characteristic curve these densities are plotted against the logarithm of the exposures which produced them.

Thus from a characteristic curve for a particular material we can read off the density value which results from a given exposure.

It is not essential to understand the exact meaning of a logarithm in order to make use of characteristic curves. The important point about a logarithmic scale of exposures is that a certain distance along the scale corresponds to an increase in exposure by a constant factor. For example, an increase of the log exposure by 0·3 always corresponds to a doubling of the exposure itself.

The characteristic curve for any one sensitive material has certain special features that are common to all.

Threshold Exposure. The threshold exposure is the point at which the density is just noticeably above that of the general background density, which is always there in the unexposed portion and which is defined as the fog level. As exposure is increased from the threshold value, the density builds up increasingly rapidly. This portion of the curve is defined as the toe. On increasing the exposure still further we reach a portion of the curve where the density increases at constant rate. This is the straight-line portion of the curve. For even greater exposures the curve begins to turn into the horizontal, this portion of the curve being described as the shoulder. The height or level of the horizontal portion defines the maximum density often denoted as D_{max}.

With some materials the density may even fall again on increasing exposure. This effect is known as solarization.

Slope. The slope of the curve at any point has a special importance. The slope is the inclination of the straight line drawn through the point and tangential to the characteristic curve. If a perpendicular line is drawn down from the point, the value of the slope is the ratio of the length of this line to the length of the exposure axis between the line and the point where the tangent cuts the axis. In terms of trigonometry, the slope is the tangent of the angle which the tangential line makes with the exposure axis.

One of the most important slopes is that of the straight-line portion of the characteristic curve. The slope of this is called the gamma of the characteristic curve and is a measure of the degree of contrast to which the emulsion has been developed.

The gradient of the curve between any two points is the slope of a line drawn between the two points. It may be defined between two exposure values or two density values. The gradient is also designated as average slope and is, for many applications, a useful measure of the contrast of reproduction.

Speed. The position of the characteristic curve with respect to the exposure scale is decided by the sensitivity or speed of the photographic material. The further to the left—i.e., towards shorter exposures—the characteristic curve is situated, the less the exposure required to produce any one density on the curve and the faster the emulsion.

The actual speed figure is based on the exposure necessary to reach a certain point on the characteristic curve. The point chosen is called the speed criterion; it differs according to the purpose for which the material is to be used and for which the speed has to be defined. For pictorial photography, for example, the speed criterion is always a point near the lower density end of the characteristic curve, since it is this part of the curve which is used in practice. For process or X-ray work a much higher density would be chosen.

CHARACTERISTIC CURVE. Density D is plotted against the logarithm of the exposure log E. Important features: V, fog level; W, toe; X, slope of straight-line portion (gamma = tan X); Y, threshold exposure; Z, shoulder.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The speed figure is derived by means of the speed formula from the exposure necessary to reach the speed point. The speed scale is as a rule so arranged that the speed increases with decreasing exposure, and the speed formula is therefore based on the reciprocal of the exposure, i.e., on 1/E.

Tone Reproduction. The shape of the characteristic curve is of great practical importance, since upon it depends the final reproduction of the tones in the original. According to the requirements of the process, materials of varying response characteristics are available. The difference between the various materials lies as a rule less in the shape of the curve than in the value of the contrast, which is most conveniently expressed by the gamma figure, or alternatively by the average slope. A material of high contrast produces a big difference in density for a small difference in log exposure, and vice versa.

TYPICAL GAMMA VALUES

Material	*Gamma*
Portrait films and plates	0·5 to 0·8
Press materials	0·5 to 0·8
General purpose films and plates, roll films ...	0·8 to 1·2
Positive cine film	up to 1·8
Negative cine film	0·65
General purpose process materials	2·0
Line materials of high contrast	4·0
"Lith" type materials	8–12
X-ray films	3·0

Controlling Contrast. With a given material, slope and gamma values are affected by several factors. The most important is development: over a certain range gamma increases with the time and/or temperature of development and is most conveniently controlled in this way.

This control method has its limits; for example, it is impracticable to shorten development too much, since the material would develop unevenly. On the other hand, extending the development time will only increase the contrast to a given value, beyond which no further increase is possible; this value is known as gamma infinity. Therefore it is essential to choose a material of approximately the correct inherent gamma.

The slope of the characteristic curve also depends on the colour of the exposing light; the gamma is low for ultra-violet, a good deal higher for blue, and often higher still for red light. For colour separation work, where the same material is exposed through blue, green, and red filters, the difference in gamma has to be compensated for by using different times of development.

Gamma varies with time of exposure; it may be considerably lower for electronic flash than for normal snapshot exposures. To compensate for this, the time of development for films taken by electronic flash should be increased by 50 per cent.

Colour Materials. For integral-tripack materials

COLOUR FILM CURVES. A colour film uses three curves, one for each layer—blue, green and red sensitive. Ideally the curves should coincide; here the blue curve has a shallower toe (too much yellow in the shadows of the colour negative or too much blue in the print) while the red sensitive emulsion curve flattens out before the others in the highlights, leaving too much red there in the print.

the behaviour of each of the three constituent layers has to be described by a characteristic curve. The material may be developed to a black-and-white image, as is always done with reversal materials, when the image does not differ from that in any multi-coated material. When the layers are developed in colour, however, the value of the densities read on a densitometer depends on the filter through which the readings are taken.

For a positive colour material, the spectral sensitivity of the densitometer for the three spectral regions should have curves which correspond to the tri-stimulus curves of colorimetry or are linear transformations of these. If these conditions are fulfilled, a grey scale will be reproduced by the material as grey, provided the three characteristic curves coincide. The material will have a uniform colour cast, if the curves are identical in shape and merely displaced parallel to one another along the log exposure axis. This cast can be corrected by interposing a suitable filter during exposure. If the slopes of the curves differ, no filter can prevent the lights and the shadows having different casts. No correction is possible if the values for fog or for maximum density differ, except by viewing the picture through a correction filter.

Meaningful densitometry of colour negative materials is more difficult, since the result can be judged only on the final positive, the layers of which have spectral sensitivities which most probably differ from the tri-stimulus curves. It is therefore necessary to make arbitrary extensions or compressions on the density scales for the negative, until nominally equal densities for the three layers, will produce grey in the final picture. When this has been achieved, the same requirements as for the positive hold for the three characteristic curves of the negative material, except that uniform fog densities may not matter if the curve shapes are otherwise identical (e.g. integral masks).

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

When characteristic curves are measured as described, the density values for any one of the three spectral regions contain contributions from each of the layers: they are integral densities. The analytical densities and thus the characteristic curves which describe the behaviour of each layer, can be obtained from the curves for integral densities by a simple transformation, if the spectral absorptions of the three dyes are known.

The value of the density in any one layer depends not only on the exposure given to that layer but also on the exposures of—and hence the densities in—the neighbouring layers. This dependance is known as the inter-layer effect, which is studied by the use of analytical densities. The inter-layer effects may produce useful masking and hence an improvement in colour saturation.

CHARGER. Type of magazine for narrow-gauge cine cameras. Makers of certain 9·5 mm. cameras frequently refer to their film loads as chargers.

In electronic flash units and portable tape recorders chargers are built in or separate units for recharging accumulators or other secondary cells used for the current suppy.

See also: *Cine camera; Flash (electronic); Magazine.*

CHARGER FOR CASSETTE. Apparatus to enable reloadable 35 mm. film cassettes to be quickly and conveniently loaded. There are two types of charger—darkroom and daylight.

Film Winder. The darkroom type is simply a film winder which grips the film spool between centres so that it can be turned by a handle. It clamps to the edge of the bench. The spool is taken out of the cassette and mounted in the winder. The darkroom light is then switched off and the end of a measured length of film or a standard refill is clipped to the spool. The handle is then turned until the whole length of film—except for two or three inches to act as a leader—has been wound on. The spool of film is then removed from the winder and fitted back into the cassette. The handle end of the winder is forked to engage with the driving pin in the spool, and the handle is prevented by a ratchet from being turned backwards.

CASSETTE LOADING. Left: *A mechanical film winder simplifies spooling up 35 mm. reloads.* Right: *A light-tight charger permits the whole job to be done in daylight.*

Daylight Charger. The daylight charger is in two parts; one is a storage container that holds a bulk length of film, the other is a light-tight box which takes the complete film cassette and has a handle mounted in the end and forked to engage the spool driving pin. Each part has a light-trapped slit through which the film runs, and they can be clamped together so that film can be fed from one to the other without being exposed to the light.

To charge a cassette, the spool is removed and the end of the film from the storage box is attached to it. The cassette is then slipped over the spool and the cassette holder is fitted over it. The two parts are then clamped together; turning the handle now draws film from the storage chamber, through the light trapped slit and on to the cassette spool.

A table supplied with the charger indicates how many turns of the handle will wind on any desired length of film.

CHEMICAL CALCULATIONS

When dealing with chemicals in photography, calculations may be required for the following purposes:—

(1) To find the amount of one chemical which can be used to take the place of a given quantity of another.

(2) To find the equivalent amounts of anhydrous and hydrated crystalline versions of a chemical.

(3) To establish the amounts of two or more chemicals which are needed for a reaction.

(4) To work out quantities required for making up solutions of given concentration of a chemical.

(5) To work out dilutions of stock and other solutions.

Substitution of Chemicals. In many processing solutions certain chemicals can be replaced by others without affecting the properties of the solution. The amounts needed are in propor-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

tion to the molecular weights of the chemicals concerned. These are worked out from tables of atomic weights.

For example, potassium bichromate can be replaced in bleaching baths by ammonium bichromate. The chemical formula of potassium bichromate is $K_2Cr_2O_7$, of ammonium bichromate $(NH_4)_2Cr_2O_7$, and the respective molecular weights 294 (2 × 39 for K; 2 × 52 for Cr; 7 × 16 for O; and 252 (2 × 14 for N; 8 × 1 for H; 2 × 52 for Cr; 7 × 16 for O). Therefore 294 parts by weight of potassium bichromate will replace or be replaced by 252 parts of ammonium bichromate.

Thus 100 parts potassium bichromate are equivalent to 100 × 252/294 = approx. 86 parts ammonium bichromate—i.e., about 7 parts of the one to 6 of the other.

Conversely, 100 parts ammonium bichromate are equivalent to 100 × 292/252 = approx. 117 parts potassium bichromate.

For any other quantity Q of ammonium bichromate therefore use Q × 117/100 or Q × 294/252 parts of potassium bichromate.

Similarly, sodium bichromate has the formula $Na_2Cr_2O_7.2H_2O$, and a molecular weight of 298. This is practically the same as for potassium bichromate, so the two can be interchanged in equal quantities.

ATOMIC WEIGHTS OF ELEMENTS IN PHOTOGRAPHIC CHEMICALS

Element	*Symbol*	*Atomic Weight*

The weights are rounded off to the nearest 0·5.

When substituting chemicals, the substituted chemical must not affect the action of the bath in any material way. In the above example of ammonium and potassium bichromate that holds true as long as the bleacher in which they are used is acid; if it becomes alkaline, it will liberate ammonia which may give rise to quite a different action. On the other hand, sodium and potassium bichromate are not likely to differ in their action at all.

Substitution by molecular or equivalent weights also does not apply to alkalis (other than strong ones like sodium and potassium hydroxide) in developers. The reason is that the activity of a developer depends on its pH value, and equivalent solutions of most of the alkalis used in developers rarely have the same pH value.

Anhydrous and Hydrated Crystalline Chemicals. Many chemicals exist in several forms with and without water of crystallization. The various forms are, of course, absolutely identical in their equivalent solutions. Calculation of the respective amounts follows the same principle as for the substitution of chemicals.

For example, anhydrous sodium carbonate Na_2CO_3, molecular weight 106, is identical, when dissolved, with crystalline sodium carbonate $Na_2CO_3.10H_2O$, molecular weight 286, or the monohydrate $Na_2CO_3.H_2O$, molecular weight 124. Thus 100 parts of crystals can be replaced by 100 × 106/286 = 37 parts of the anhydrous salt, or by 100 × 124/286 = approx. 43 parts of the monohydrate.

Chemical Reactions. Sometimes a chemical has to be made in solution by the interaction of two or more other chemicals. In that case the required amounts can be calculated from the equation of the reaction.

For example, sodium metaborate can be prepared by mixing solutions of sodium hydroxide and borax. In practice that means that the latter two chemicals can be used in a developer specifying sodium metaborate. The reaction is:—

$$2NaOH + Na_2B_4O_7.10H_2O + 5H_2O = 4(NaBO_2.4H_2O)$$

(The water of crystallization has been included in the equation to simplify calculation of equivalent amounts of the crystalline chemicals, but it does not take part in the reaction.)

The weights reacting are:—

$$2 \times 40 + 382 \quad (+ 90) = 4 \times 138$$

Note that both sides of the equation must balance quantitatively—i.e., in this case, both sides add up to 552.

Thus 552 parts of sodium metaborate are obtained by mixing 80 parts of sodium hydroxide (in solution) with 382 parts of borax. Therefore 100 parts of metaborate require 100 × 80/552 = approx. 14·6 parts sodium hydroxide plus 100 × 382/552 = 69·5 parts borax. In this particular case it is better

Note.—Ammonium salts should not be used in developers or other alkaline solutions unless specifically stated.

to take a slight excess of borax rather than of hydroxide, so this ratio can be simplified to 1 part hydroxide plus 5 parts borax making 7 parts metaborate.

As another example, sodium metabisulphite can be used instead of sodium bisulphite. The latter is in fact formed on dissolving the metabisulphite:—

$$Na_2S_2O_5 + H_2O = 2NaHSO_3$$

From this, 190 parts metabisulphite yield 208 parts of bisulphite. Other quantities of sodium metabisulphite—or of potassium metabisulphite—can then be calculated as already described.

Solution Strengths. The strength of concentration of solutions can be quoted in various ways: weight per volume (W/V), weight per weight (W/W), volume per volume (V/V), or percentages (%). There are also the chemical notations of molarity and normality.

Weight per volume—e.g., grams per litre—solutions are made by dissolving the requisite number of grams in the minimum amount of water, and then adding enough water to make 1 litre. The procedure is analogous for ounces or grains per pint or any other unit. With a solution containing A grams per litre, B c.cm. are equivalent to A × B/1,000 grams; if the solution contains C grains per pint, D fluid ounces are equivalent to C × D/20 grains, and so on.

Weight per weight solutions—e.g., X grams of solute per 1,000 grams of solution—are made by dissolving X grams in 1,000-X grams of solvent. This notation is comparatively rare in photographic use. Proportionate amounts are calculated in the same way as for weight per volume solutions.

Volume per volume solutions—e.g., c.cm. per litre—are made by taking the requisite number of c.cm. and adding enough water to make 1 litre (ounces per pint or any other unit are similar). This notation is often used for solutions of liquids.

Percentage solutions may be weight per volume or per weight, or volume per volume, and in each case the figure specifies parts per 100. The most common system is that of weight per volume, as it is easiest to handle. It is, however, important to state which system is used; for instance a 10 per cent solution of sulphuric acid on a weight per volume basis is only just over half as strong as a 10 per cent volume per volume solution.

Molar solutions specify the number of gram-molecules per litre. For instance sodium sulphite (Na_2SO_3) has a molecular weight of 126; a molar solution therefore contains 126 grams per litre. (Water of crystallization is ignored in working out the active concentration of molar solutions, but has to be taken into account when weighing out the crystalline chemical.) A solution of 12·6 grams per litre is called deci-molar solution and written 0·1M. Other strengths are labelled accordingly.

Normal solutions contain the gram-equivalent weight per litre. This may be the same as the gram-molecular weight, or it may be a simple fraction of it, depending on the chemical concerned. Again there are deci-normal (0·1N), twice normal (2N) etc., solutions.

Using Percentage Stock Solutions. Provided the chemicals keep well in solution, and are used at a low concentration, the ingredients of many formulae can be stored in individual solutions of a fixed percentage strength. This eliminates weighing out and dissolving the chemicals afresh each time a fresh processing bath is required. The system is specially useful where several baths with the same ingredients, but

in different proportions, are employed from time to time—e.g., with reducers and intensifiers of different degrees of activity.

For convenience all the solutions may be made up to 5 or 10 per cent. To make up a formula, simply multiply all the weights in grams by 20 or 10, mix the corresponding number of c.cm., and make up to the final volume with water.

Owing to the poor keeping qualities of developing agents in solution by themselves, this method is not generally suitable for developers, although separate stock solutions —e.g., developing agents plus preservative on the one hand, and alkali on the other—are practical.

Diluting Percentage Solutions. To dilute a solution of A per cent to make a solution of B per cent, take 100 × B/A parts and add water to make up to 100 parts.

For example, to dilute a 40 per cent solution to 15 per cent, take 100 × 15/40 = 37·5 c.cm. and make up to 100 c.cm. again with water. If the original solution contained 40 per cent of the chemical, i.e., 40 grams per 100 c.cm., 37·5 c.cm. of it will contain 40 × 37·5/100 grams = 15 grams, which makes 15 per cent if diluted to 100 c.cm.

Dilution of Stock Solutions. Many processing solutions, notably developers, are conveniently made up in concentrated stock solutions and diluted for use. The solutions keep better that way and are easier to store.

The recommended dilution may be specified in several ways.

(1) Diluting x times. To dilute a solution a given number of times—e.g., 5 times—take 1 part stock solution and add (x − 1) parts (in this example, 4 parts) of water to make a total of x—i.e., 5 parts of working solution. If a given final volume is required, the amount of stock solution used will be one-fifth.

(2) Diluting to make x parts. This is the same as diluting x times.

(3) Diluting with y parts of water. This means that the working solution consists of 1 part stock solution plus y parts of water. To obtain a given final volume, this has to be divided by (y + 1) for the amount of stock solution required. For instance, for 400 c.cm. of working solution, obtained by diluting the stock solution with 4 parts of water, the required amount of stock solution is 400/(4 + 1), or 80 c.cm.

(4) Diluting 1 : y. This is the same as diluting with y parts of water.

Note that diluting with y parts of water (or 1 : y) is the same as diluting (y + 1) times, to make (y + 1) parts. For instance, diluting with 4 parts of water means diluting 5 times, i.e., to make 5 parts in all. L.A.M.

CHEMICAL FOCUS. When a beam of parallel light rays falls on a convex lens, the rays are bent towards the axis. If the lens is uncorrected for chromatic aberration, the invisible actinic rays intersect the axis at a point or points (the chemical focus) closer to the lens than the intersection of the visible rays (the visual focus).

In a fully corrected lens the chemical and visual foci coincide.

See also: *Aberrations of lenses; Lens.*

CHEMICAL FOG. Veil of metallic silver deposited all over the negative. Heavy fog is caused by prolonged or overactive development, but a certain amount of chemical fogging always arises during development.

See also: *Fogging.*

CHEMICALS. The term "photographic chemicals" is apt to suggest a range of organic and inorganic substances which are manufactured exclusively for photographic use. In fact, most

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

of the chemicals used in photography have important application in other fields.

There are about fifty of these chemicals in common use including the developing agents, sodas and other chemicals used in black-and-white processing and the more popular reducers, intensifiers, toners, etc. This figure rises to about eighty with the chemicals used in colour processing and other more specialized work. Almost all these substances are readily available as branded chemicals in quantities to suit every requirement.

In a wider sense the term "photographic chemicals" has also come to include the many proprietary developers, fixers and other ready-made processing solutions which have become a feature of modern photographic practice.

Purity. Chemicals usually bear on their labels such terms as Commercial, Technical, Pure, Recryst., B.P. (British Pharmacopoeia), B.P.C. (British Pharmaceutical Codex), or A.R. (Analytical Reagent). To a chemist these descriptions give a more or less reliable indication of their purity, but the photographer might well be confused by the various grades of a particular chemical which he could buy.

For most purposes B.P. or B.P.C. grade chemicals made by the larger manufacturers of fine chemicals are suitable. A.R. chemicals are even purer, especially when backed by commercial trade marks for this grade, but are rarely required for photographic use and are usually very expensive.

The best policy generally is to buy the branded chemicals which are supplied specifically for photographic use. It can be assumed that the manufacturer employs analytical and photographic tests to ensure that a satisfactory and standard product is supplied at a fair price. He will also distinguish between impurities which are harmless and those which are undesirable—a job which would be quite impossible for the practical photographer. For example—a sample of anhydrous sodium sulphite containing one or two per cent of moisture or inert sodium sulphate would be considered satisfactory for photographic use, but a high percentage of carbonate, a trace of hypo or a few parts pe million of copper would be extremely undesirable.

There is always an element of risk in using unbranded chemicals, particularly commercial or technical grades, since there is no guarantee against variation from batch to batch or against the presence of undesirable impurities.

Forms. Solid chemicals are frequently classified as "crystal", "granulated" or "powder" according to their physical form. This classification can be misleading; although some chemicals naturally occur as powder or in granulated form, others consist of very small crystals or are produced by grinding or pulverizing large crystals.

In some cases, notably sodium sulphite, sodium carbonate and thiosulphate, the term "powder" has come to indicate the dried or anhydrous form of the chemical; but all powdered chemicals are not anhydrous. In the cases of borax, boric acid and potassium bromide the crystal and powder forms are identical in composition.

In general, powdered and granulated chemicals are easier to handle and they dissolve more readily than the larger crystal forms. If, however, a chemical is liable to deteriorate on exposure to air, e.g., potassium ferricyanide, potassium metabisulphite, the larger crystals are more stable.

A number of chemicals contain in their crystal form a quantity of water of crystallization. In some cases this can be partially or entirely removed by drying under carefully controlled conditions, to give free-flowing granular powders which are known as dried, desiccated or anhydrous chemicals.

Anhydrous chemicals contain more of the active ingredient weight for weight than the crystals and allowance must be made for this when making up formulae in which crystals are specified. For example—100 parts sodium carbonate cryst. = 37 parts dried; = 43 parts monohydrate. 2 parts sodium sulphite cryst. = 1 part dried. 8 parts hypo cryst. = 5 parts dried. 13 parts sodium acetate cryst. = 8 parts dried.

Anhydrous chemicals are usually more satisfactory for general photographic use. They are easier to store, weigh, and dissolve, and are less affected by high temperatures. Although their cost per pound is greater than that of the crystals, they are proportionately stronger and are often cheaper in actual practice.

One drawback of anhydrous or desiccated salts is that they may cake together in one lump if stored in slightly damp conditions. This applies as much to individual chemicals as to mixtures such as acid fixing powder. Once caked together, the chemical usually has to be broken up before dissolving, as large lumps take a long time to go into solution.

Using Individual Chemicals. The small user will generally buy developing agents in ounce bottles, and carbonate, sulphite and hypo in pound bottles or tins. The ounce and pound containers correspond to all intents and purposes, to the 25 gm. and 500 gm. containers. Even so, the cost of even a modest stock of the chemicals necessary to develop and fix will be at least 20s., not counting the cost of a balance and weights.

The main advantage of preparing solutions from individual chemicals is that any one of a wide variety of published formulae can be made up as required at comparatively low cost. This is economical for the large user, as the solutions can be made up in bulk. For the smaller user who processes an occasional film now and again, ready packed chemicals are much more convenient and handier.

Made-up Formulae. Packed chemicals made up to specific formulae are usually either supplied

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

in powder form or as concentrated liquids. Both forms have their advantages but of recent years the convenience of liquid developers has greatly increased their popularity.

Powders, which are usually packed in cartons, foil, plastic envelopes or tins, are available in all sizes from the small individual pack costing a few pence to the largest tin making 50 gallons or more for bulk processing. Powdered chemicals are compact, easily stored and least liable to damage in transit.

Liquid preparations have the two-fold advantage of economy and convenience and many photographic solutions are now available in this form. They can usually be diluted to four or five times their volume for contact printing, to five to ten times for bromide printing and dish development of negatives and up to twenty times or more for tank development.

Storage of Solid Chemicals. A safe rule is to protect photographic chemicals from exposure to air, moisture and excessive heat and to avoid any possibility of contamination with metals or other chemicals. This implies the use of air-tight glass, plastic or stoneware containers.

Developing agents should be stored in air-tight bottles or lined tins with close-fitting lids. The chief hazard is oxidation by exposure to air, a process which is accelerated by dampness. If this is avoided, most developing agents will keep in good condition for years. Slight discoloration has no adverse effect, but a few developing agents—e.g., Amidol and para-phenylenediamine—deteriorate more rapidly and should not be stored for longer than about a year.

Anhydrous or dried chemicals absorb moisture from the air and some deteriorate in other ways if they are not stored in air-tight containers. Sodium sulphite oxidizes to the inert sulphate; sodium carbonate is slowly converted to bicarbonate. Dried hypo does not deteriorate chemically but solidifies to a rock-like mass.

Crystal chemicals containing water of crystallization (such as sodium sulphite, sodium carbonate and hypo) become powdery on exposure to air. This drying-out or efflorescence tends to increase their strength, but some, such as sulphite, also deteriorate chemically. The danger in these cases is that the chemical is no longer uniform in composition and it is impossible to be certain of the extent of the deterioration by casual examination.

Some photographic chemicals are deliquescent—i.e., they absorb moisture from the air and liquefy. These include the thiocyanates, hydroxylamine hydrochloride, sodium sulphide and the caustic alkalis. In such cases the use of completely air-tight containers is essential and it is usually more convenient to prepare stock solutions of these chemicals. Some also deteriorate quite rapidly: caustic alkalis absorb carbon dioxide and are gradually converted to carbonates; sodium sulphide is converted to a mixture of compounds including hypo which makes it unsuitable for toners.

Storage of Solutions. Nearly all photographic solutions deteriorate on exposure to air and are best stored in completely air-tight bottles. They should also be protected from strong light and extremes of temperature.

Some solutions, such as those containing Amidol and some colour developers, are unstable and should not be stored; most developers in very dilute solutions deteriorate quite rapidly, particularly after use.

Concentrated developers, including proprietary liquid developers, usually keep well in reasonably full, airtight bottles. In most cases any serious deterioration is indicated by a marked darkening in colour and it is always unwise to use developers in this condition. Once the bottle has been opened, an air space above the contents is inevitable; this will have no serious effect although concentrated developer should not be stored for a long period in a bottle which is more than, say, two-thirds empty.

Fixing baths will normally keep for several months, but eventually decompose giving a yellow deposit of sulphur.

Stoppering. Any bottle containing a photographic solution should have an efficient stopper. Corks quickly become sodden and porous and only of temporary use.

Glass stoppers are excellent for acids, solvents, etc., but are unsuitable for use with developers and alkaline solutions, owing to the risk of their becoming cemented firmly into the bottle neck.

Well-fitting soft rubber bungs, or plastic screw caps with rubber or plastic wads are the most satisfactory closures. R.L.T. & A.R.P.

CHEMICAL SYMBOLS. Internationally agreed letters or groups of letters signifying individual chemical elements. Generally these symbols are the initial letters or abbreviations of the names of elements; in some cases the Latin or Greek names are used—e.g., H for hydrogen, O for oxygen, Ag (argentum) for silver, and so on.

Simple Formulae. The formula of a chemical compound is made up of such symbols and shows what elements, and how many atoms of each, are contained in a molecule of the compound. Thus the formula $Ag\ NO_3$ for silver nitrate indicates that each molecule of silver nitrate contains one atom of silver (Ag), one atom of nitrogen (N) and three atoms of oxygen (O). Similarly, the formula $Na_2S_2O_3$ for sodium thiosulphate shows two atoms of sodium (Na), two atoms sulphur (S), and three atoms oxygen (O).

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The same symbols are used in formulating chemical reactions. There they show the nature and proportions of molecules taking part:—

$$CaCl_2 + 2AgNO_3 \rightarrow Ca(NO_3)_2 + 2AgCl$$

Here one molecule of calcium chloride (consisting of calcium Ca and chlorine Cl) reacts with two molecules of silver nitrate to form one molecule of calcium nitrate and two of silver chloride.

The numbers of each kind of atom on each side of the equation must be the same. The symbols in the equation thus also indicate the equivalent quantities—established by reference to atomic weight tables—of materials used up and produced. The above equation therefore shows that 2×170 parts by weight of silver nitrate (atomic weights $Ag = 108 + N = 14 + 3 \times O = 3 \times 16$, total 170) form 2×143.5 parts of silver chloride ($Ag = 108 + Cl = 35{\cdot}5$, total 143·5).

With many reactions—especially those taking place in solution—the symbols in fact signify the quantitative reaction only; the actual mechanism of the interaction between the molecules may be more complicated.

Structural Symbols. In organic chemistry where large and complex molecules are involved, the structure of a compound may involve large numbers of similar atoms. There structural formulae are often required to show the arrangement of the elements, since large numbers of compounds may have the same empirical formula. Thus a formula $C_6H_6O_2$ might correspond to a hypothetical compound

$$CH \equiv C - CH = CH - CH_2 - COOH$$

or to

or to

The first of these would probably be too unstable to exist, but the other two are the developing agents hydroquinone and pyrocatechin respectively.

The structure

which signifies benzene occurs very frequently in organic chemistry, and is often replaced by a structural symbol, so hydroquinone may be written as

each corner of the hexagon corresponding to a carbon and a hydrogen atom (CH), except where something else (here OH) is attached, which replaces the hydrogen atom.

Other structural symbols are the lines which join the atoms together. Single, double, and triple lines indicate different types of chemical bond, and thus show quite a lot about how the compound is likely to behave. L.A.M.

CHEVALIER, CHARLES LOUIS, 1804–59. French optician and camera obscura manufacturer. Made apparatus for Niépce and gave his address to Daguerre for whom he was also working. In 1839 made lenses for the Daguerre-Giroux cameras. In 1840 introduced the Photographe, a portable daguerreotype camera. Produced photomicrographs as early as March 1840. Chevalier was one of the earliest French photographic writers and dealers. Biography by Arthur Chevalier (Paris 1862).

CHEVREUL, MICHEL EUGENE, 1786–1889. French chemist. Carried out important researches on dyes and colouring matters and particularly their behaviour under the action of moisture, light and heat. In 1849 he studied the action of light on Prussian blue and many other colouring matters and explained the part played by oxygen and moisture in bleaching. Biography by Malloizel (Paris 1887).

CHIAROSCURO (from Italian—chiaro = light + oscuro = dark). Light and shade effect. In art, the manner of indicating transition from one tone into the other or of contrast between them. The term nowadays has more generally come to mean the way things are picked out by light or submerged in shadow.

CHILDREN. A good child photograph should look as though the camera had caught the subject unawares. Seen in this way the child looks natural and makes the best photograph. This result cannot be achieved by forcing the youngster to pose, or it will look stiff and self-conscious. Children have a will of their own; they can be made to pose naturally, but it must be done by kindness and understanding.

A successful child photographer must be so practised in the technical side of his work that he can forget about it and bring all his understanding and diplomacy to managing his subject. If he is preoccupied with technicalities he is bound to miss opportunities. He must also be able to deal tactfully with the child's mother. Small children usually feel safer when the mother is near; around the age of two they tend to cling to her, and she may even have to be included in the picture. But with older children, there are times when a fussy mother can be an embarrassment to both the photographer and his subject. No child can look natural if it is being constantly tidied and told to sit up straight and smile. The photographer

CC-0. Agamnigo Digital Preservation Foundation, Chandigarh

must persuade the mother to wait in another room if he hopes to turn out good pictures.

Being photographed is often an upsetting experience for the child. Often it has been put into clean clothes, given an extra wash, and had its hair freshly brushed before being brought along to the studio where its surroundings are completely unfamiliar. Under such circumstances it is practically impossible to get a natural likeness. At home, the child gets over all the fuss more easily and the photographer has a better chance to get it into the right mood to be photographed.

Things are much easier if the youngster can be taken when it is busy out of doors. Children playing in the open, or watching a Punch and Judy show, or the animals at the Zoo, very soon forget all about the camera. And once the child can be made to stay in one spot and forget the camera, most of the difficulties vanish. Generally the answer is to get it interested in some activity like playing with a toy, reading a book, winding a musical box, or blowing soap bubbles.

The experienced child photographer wins the co-operation of his subject by treating it as an equal. He sets out first of all to make friends with the child, even explaining the camera to it, letting it look through the finder, or help to rig up the lamps if it is old enough.

The Background. A suitable background is essential to a good child photograph. It should offer a contrast to the subject by being lighter or darker, and it should not be fussy. Indoors, a plain wall or a window will do, and it should have some light on it—black backgrounds are only for special effects. Out of doors, the sky, a hedge, or part of the house can make a good setting. In most cases the subject should be well away from the background so that it can be rendered sharp while the background is thrown out of focus.

Viewpoint. Generally the viewpoint is chosen as close as possible so that the subject fills the whole of the negative area. There are exceptions, as when the child is seen as part of the landscape, or when it is running about, but mostly the expression is the important thing, not the surroundings.

The camera is best used on the same level as the child; children always look more interesting when they are seen on their own level. The photographer can get down on to the floor where the child spends so much of its time, or he can put the child on the table or in a high chair, or even on top of a wall. Such positions also make it more difficult for the child to wander out of range.

There is no reason why the camera should look down simply because it is fitted with an eye-level viewfinder unless, for example, the child is lying in bed.

Lighting. With child photographs, the simpler the lighting, the better. Indoors, good basic lighting is given by a main light shining at about forty-five degrees and from slightly above the camera, with a second light farther away directed to soften the shadows and put highlights in the eyes. The lamps are then altered according to the position the child takes up. If there is any daylight, it may be used to advantage to replace the fill-in lamp. There may even be enough light coming through the window to make extra lights unnecessary and low sunlight coming through the window may be used with only a reflector for the shadows. Sometimes a light hanging above the child will accentuate the hair, and it is often the only way of making fair hair look really fair.

The background, however, may call for a lamp to itself.

For softly lit child studies, where only one light source (flash or photoflood) is available, the bounce light technique is ideal. This means directing the light at a suitable reflector such as a nearby wall or ceiling and using the reflected light to illuminate the subject. Such reflected light is, of course, weaker than direct light and calls for more exposure. With flash, use one and a half times to double the normal guide number for direct light. Remember also to count the distance as the path from the flash to the reflecting surface plus from the latter to the subject. For colour photography, the reflecting surfaces should be white or a neutral light grey.

Out of doors, weak, diffused sunshine is the most suitable lighting. In direct sunshine, a reflector should be used. This may be a sheet of plywood or card covered with silver paper, a white cloth, or even a newspaper. With backlighting there is no tendency for the child to screw up its eyes, and it can tolerate the soft reflected light more easily than direct sun.

Generally light coming from the direction of the camera is unsuitable; side or backlighting gives much better modelling.

Flashlight is particularly suitable for photographing children who cannot stand strong lights, and for action photographs indoors. It can also be used instead of a reflector out of doors. The general principles of lighting apply. It is better to have the flash at some distance from the camera in order to get modelling. In a medium sized room, with bright walls, there will be sufficient reflection to prevent heavy shadows.

A reflector or a second, preferably weaker flash can be used to advantage. The background should be either lit separately or it should be near enough to the child to get some light on it. You have to watch windows, mirrors and pictures which might reflect in the background. It is possible to get reasonable results with a box camera (on a tripod) and open flash. W.S.

CHINA. As early as 2,450 years ago, ancient Chinese scientists already had considerable optical knowledge and an understanding of the principles of light sensitivity.

In the fifth century B.C., the Chinese scientist and philosopher Mo Tzu expounded the relationship between the fundamental optical principles of reflection, the propagation of light in a straight line, and the formation of inverted images by light passing through a pin-hole. He also explained the relationship between an object and its image in a flat, concave or convex metal mirror.

In the fourth century B.C. a book entitled *Lord Chou's Notes on Technology* recorded the method of making fire by concentrating sunlight with a concave mirror.

A book entitled *Huei Nan Tzu* published in the Chin dynasty, 2,100 years ago, contains the following extract: "Cut a ball of ice, lift it to face the sun and put some dry grass under its shadow; fire will be created." This was a clear description of how light can be focused to a point through a convex lens.

In the North Sung dynasty (A.D. 960–1127) a scholar named Shen Kwa made a detailed and systematic explanation on the law of light in his *Pen Talk of the Dreamy Stream.* At that time the study of light already existed. It was called *Ke Shu* (The Art of Optics).

A Chinese lecturer at the University of Hong Kong claims to have found traces of china plates made sensitive to light by a chemical process 2,000 years ago. These plates, he says, might have been turned into negative pictures if used in combination with a camera obscura. He argues, therefore, that the main principles of photography were known in China 2,000 years ago.

Cameras were introduced into China around 1840. In 1845 (the twentieth year of the reign of Emperor Tao Kwang of the Chin dynasty) a scholar named Chou Shou-chang mentioned photography in his *Ssu Yi Tang Diary.*

After the May Fourth cultural movement in 1919 photography made a marked progress. During the years between 1923 and 1937 various photographic organizations were set up in Peking, Shanghai, Canton and other cities. Many books and magazines on photography were published. Photographic exhibitions were held on many occasions. During the War of resistance against the Japanese invasion, China's progressive photographers began to go amongst the people in order to record their life and struggles. This marked the beginning of a new stage in photographic progress.

After the founding of the People's Republic of China, photographic work developed rapidly with the steadily rising living standards. In the past few years, the ranks of photographers have greatly increased and photography has been widely used in industry, medicine, education and in the Press; it is also popular among the people.

Press. Chinese newspapers use large numbers of photographs in various forms. The major daily papers in China issue a full page spread of pictures every week, containing 12 to 15 photographs. In addition, they regularly devote several columns to photographic features and illustrate the news with photographs. Figures show that certain outstanding photographs often get a simultaneous circulation of more than five and a half million.

The Hsinhua News Agency supplies prompt news photographs to all newspapers and magazines in the country and periodically issues photographs for exhibition. In order to speed up the delivery of news photographs, a wide network for the radio-transmission of photographs, covering China and other countries, has been set up.

During the past few years, illustrated magazines have won wide popularity. The *China Pictorial* is published in seventeen languages—including Han, Mongolian, Tibetan, Uighur, Korean, Russian, English, French, Japanese, Indonesian and Spanish. *The Nationalities Pictorial* is published in Han, Mongolian, Tibetan, Korean and Kazakh. *The Liberation Army Pictorial* is widely read among the armed forces and its circulation has been growing every year. In addition there are provincial and regional pictorials such as the *Kwangtung Pictorial*, the *Sinkiang Pictorial*, etc.

Other magazines carry large numbers of photographs. Seventy per cent of the magazines use photographs for their front and back covers, and some of them devote special pages to photo pictures.

Photographic book publishing has made great progress, and the various publishing houses put out a great variety of works on photographic theory and techniques, as well as popular books. During the past few years a number of picture books have been published, among them being *China*, *Peking*, *Shanghai*, *Heilungkiang*, and *Inner Mongolia.* Their content is rich and varied, and the quality of photography and printing is good.

The Chinese people take a great interest in the photographic display windows in shops, schools, factory clubs, village cultural pavilions and country fairs, where they can see reflected in them their own life and work.

Lantern-slides are likewise used in large numbers. These have reached every remote corner of the country. In schools, they are used for visual education. In the villages educational slides on science and history, etc., are often projected out of doors at night. Pictorial albums, post cards and calendars are issued regularly by various publishing houses and photography is widely employed in economic construction and scientific research.

Science. Since early 1953, China has established aerial photographic survey teams to investigate and survey forest resources. These teams have photographed the forest areas in

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

the Tahailin regions, the Greater and Lesser Khingan Mountains of Northeast China, and the Altai and Tienshan Mountains. Photography was also used in the great afforestation projects of 1954, when 2,700,000 acres of forest belt were planted for crop protection, coastal defence, water conservation or timber production.

Photomicrography is used in agricultural research on pest control and crop growth, and also in medicine.

China also employs photography in industry, astronomy, geology, physics, chemistry, medicine, archaeology, and water conservancy. In the water conservancy project of the Huai River, for instance, photographs were taken for records and research through every stage of the work. All the main conservancy projects in China, including the ancient Tukiangyen irrigation system, have been photographed for research purposes. In one case, a photograph of the Shihlungkiang Reservoir in Hupeh province prompted on-the-spot research which revealed that the project had certain advantages over others.

Amateur Activities. With the steady rise in living standards, amateur photography is rapidly growing. Photographic shops with printing and developing services are plentiful in the Peking shopping centres as well as in the places of recreation and culture. With the rapid increase in the number of photography fans, the trade is experiencing a minor boom. Amateur photography clubs are also on the increase and extending their influence. The Society of Photography in Peking University has been successful in raising the students' standard of photographic technique and in fostering their interest in photography.

As a result of these developments the industry as a whole is growing. The supply of photographic materials and equipment has considerably increased in recent years. Cameras, various types of films, photographic papers, enlargers, modern optical glass, electronic flash units, glazers, printers, copying cameras and photographic chemicals have all been put into planned production, and their quality is rising steadily.

Society. The Photographic Society of China a nation-wide organization was founded in Peking in December 1956, and aims mainly at encouraging creation in photographic art and raising the level of photographic theory. It is a member of the All-China Federation of Literary and Art Circles. The Society holds an annual national exhibition and in addition regularly sponsors one-man shows and exhibitions on special themes. It publishes an annual collection of photographs and edits the bimonthly magazine *China Photography*.

The Photographic Society of China organizes forums of various kinds, holds discussions on photographic problems and organizes visits to factories, the countryside, construction sites and famous beauty-spots to take photographs. It also arranges lecture tours for photographers and helps to provide training for young photographic workers and amateurs.

An Exhibition of Chinese Photographic Art has been seen in many countries. The Society takes part in international activities and every year Chinese photographers send their works to international exhibitions, in order to promote friendship and mutual understanding between the peoples of China and other countries. Many foreign countries have sent exhibitions to China. The Photographic Exhibition on Cuba's Revolution, held in China in the spring of 1963, attracted more than a million people.

There are 18 affiliated branches of the Society in the country's provinces, municipalities and autonomous regions.

The Future. The State is devoting increasing attention to the training of photographers. In addition to short-term photographic training classes in various organizations, courses on news photography have been instituted in noted universities, such as Peking and Futan Universities, with the aim of training news photographers. The Shanghai People's Fine Arts Publishing House has published several popular books on photography.

As photography is close to the life of the people of China and serves their interests, it holds an important position in public estimation. Although it is on the threshold of its development, the experience of the past few years shows that it has wide prospects. S.-h.S.

CHLORHYDROQUINONE. Developing agent used in warm tone developers. Similar in use to hydroquinone.

See also: *Chlorquinol.*

CHLORIDE PAPER. Development paper coated with an emulsion of silver chloride. They are known generally as contact papers and less often, nowadays, as gaslight papers.

See also: *Papers.*

CHLOROBROMIDE. Light-sensitive emulsion composed of a mixture of silver chloride and silver bromide. Emulsions of this type are coated on development papers and lantern plates. They possess the property of giving warm tones by normal development processes.

CHLORQUINOL. Adurol; chlorhydroquinone; chloro-para-dihydroxybenzene. Developing agent particularly in warm tone developers.

Formula and molecular weight: $C_6H_3(OH)_2Cl$; 144·5.

Characteristics: Fine white crystalline powder.

Solubility: Fairly soluble in water.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CHROMATIC ABERRATION. Axial aberration of simple lenses, causing light of different colours to fall in different planes of focus.

See also: *Aberrations of lenses.*

CHROMATICITY. Term for describing objectively the colour quality of a visual stimulus (e.g. a coloured light or a surface) irrespective of its luminance. Chromaticity and luminance together completely specify a colour stimulus.

In the C.I.E. system of colour measurement chromaticity is expressed mathematically by two numbers, x and y, termed chromaticity coordinates, and a diagram showing the ranges of these coordinates for all colours is termed a chromaticity diagram.

See also: *Colour measurement.*

CHROMATYPE. Several variants of photography on paper using chromium salts. Robert Hunt, who coined the name, announced his process in 1843. The paper was prepared with a solution of sulphate of copper and potassium bichromate. It produced direct positive photogenic drawings, but was not sensitive enough for use in the camera.

CHROME ALUM. Potassium chromium sulphate. Standard ingredient in some hardening baths.

See also: *Alum, Chrome.*

CHROME FILM. Alternative name for orthochromatic film; now obsolete. At one time the ending "chrome" to trade names of films used to indicate an orthochromatic material. Since such films fell into almost universal disuse for general amateur photography, a number of well known film names with the "chrome" ending became panchromatic but retained the old description.

Among colour films the ending "chrome" frequently signifies a reversal material for producing transparencies, especially in the U.S.A. (where the ending "color" signifies a negative colour material). In Europe this distinction is frequently not made.

See also: *Colour materials; Negative materials.*

CHROMIC ACID. Sensitizer used in some formulae for the carbon and carbro printing processes.

See also: *Chromium trioxide.*

CHROMIUM AMMONIUM SULPHATE. Hardener for plates and films used in some stop baths and fixing baths.

See also: *Alum, Chrome.*

CHROMIUM POTASSIUM SULPHATE. Standard ingredient in some hardening baths. Popularly called chrome alum.

See also: *Alum, Chrome.*

CHROMIUM TRIOXIDE. Anhydrous chromic acid; chromic anhydride. Sensitizer for carbon and carbro processes.

Formula and molecular weight: CrO_3; 100.

Characteristics: Very hygroscopic red crystals, forms chromic acid in solution.

Solubility: Highly soluble in water, soluble in acetic acid and ether.

CHROMOGENIC DEVELOPMENT. Process of producing a colour image simultaneously with a silver image in a photographic emulsion.

An image in colour, formed from a dyestuff, may be obtained by (*a*) the generation, or (*b*) the destruction of a dye during the process of the development of a silver image. The generation of a coloured body by development is the basis of most commercial colour processes today.

Dye destruction, which is noted here only as an interesing corollary, finds application in the formation of colour correcting masks in integral tripack materials.

The formation of a coloured image during development has been known since early times in the case of development by pyrogallol, and the fact that a dye image remained even after the silver was bleached away was demonstrated by Liesegang in 1895. Homolka (1907) carried this further by using as developers substances which would oxidize to good dyes. With indoxyl and thio-indoxyl he obtained blue and red images.

R. Fischer first obtained patents (1912) on colour development processes of this sort. He showed that an existing silver image could be bleached to silver halide and redeveloped to give a colour image and, in 1914, obtained patents covering the addition to the developer of substances that would couple with the oxidized developer to give a dye. For example, tri-chlornaphthol was to act as a coupler for oxidized paraphenylenediamine.

In the first stage of development the developing agent reacts with the silver halide, e.g. silver bromide to give oxidized developer (a quinonediamine), soluble halide and silver. The oxidized developer reacts with the coupler to give a leuco-dye. The leuco-dye reacts with further silver halide and is oxidized to the final dye. In theory, four atoms of silver are reduced in the formation of one molecule of dye.

The coupler can be added to the developer as mentioned above, but the control of the developer and of the entire processing is much simplified if the coupler is incorporated in the emulsion.

For integral, multilayer colour films it is essential that the couplers remain in their proper layers. This is achieved either by making the coupler molecule too large to permit diffusion through gelatin, or by dissolving the coupler in droplets of a fatty substance dispersed within the gelatin.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

For a three-colour subtractive system, the developing agents and couplers have to be selected with care so as to provide dyes of the correct spectral absorptions. With p-aminodiethylaniline as developing agent, phenols and naphthols give cyan dyes, certain pyrazolones give magenta dyes, and esters such as ethylacetoacetate give yellow dyes. A wider range of couplers is available where chromogenic development is intended for toning rather than for subtractive colour reproduction. The following developing agents and couplers have been recommended:—

Developers:	paraphenylenediamine	violet
	paratoluidinediamine	blue
	dimethylparaphenylenediamine	blue-green
Couplers:	alpha naphthol	blue
	2 : 4 dichlornaphthol	blue-green
	trichlornaphthol	green-blue
	pentabromonaphtol	green
	p-nitrobenzylcyanide	yellow
	1-phenyl-3-methyl-5-pyrazolone	magenta-red

See also: *Colour film principles; Colour film processing.*
Books: *Developing* by C. I. Jacobson (London).

CHRONOLOGY OF PHOTOGRAPHIC INVENTIONS

Before 1700: Camera obscura and magic lantern.

1725 Schulze, J. H.: Experiments on light sensitivity of silver salts; contact images (from stencils) on liquid mixtures of chalk and silver nitrate in a bottle; no fixing.

1777 Scheele, C. W.: Blackening of silver chloride in the violet and the blue of the spectrum quicker than by other colours.

1800 Herschel, Sir William: Discovery of infra-red.

1800 Wedgwood T.: Contact copying of silhouettes, leaves, etc., on leather sensitized with silver nitrate; no fixing.

1801 Ritter, J. W.: Blackening of silver chloride by ultra-violet.

1816 Niépce, J. Nicéphore: Camera photographs on paper sensitized with silver chloride. Partially fixed.

1819 Herschel, Sir John F. W.: Discovery of thiosulphates and of the solution of silver halides by "hypo".

1822–5 Niépce, J. Nicéphore: Copying of engrainings on glass, zinc and pewter sensitized with bitumen. Further attempts at direct photography.

1826 Niépce J. Nicéphore: First photograph from nature on pewter sensitized with bitumen (exposure 8 hours). Bellows for photographic camera; iris diaphragm.

1827 Niépce, J. Nicéphore: First prints from etched heliographic plates.

1835–7 Daguerre, L. J. M.: Daguerreotype (direct photography on silvered copper plates with a silver iodide surface); development of the latent image by mercury vapour. 1837, fixing with salt solution.

1835 Talbot, W. H. Fox: "Photogenic drawings", copied on paper sensitized with silver chloride; fixed with potassium iodide or by prolonged washing in salt water. Also tiny camera photographs.

1839 Reade, J. B.: Photomicrographs in the solar microscope on paper sensitized with silver nitrate and gallic acid (by printing out or by development with gallic acid); fixing with thiosulphate.

CHRONOPHOTOGRAPHY. Photographic method of analysing an action by taking a series of still pictures at regular intervals throughout its duration. This method of analysing motion is very similar to cinematography, although the apparatus used is quite different.

Muybridge's Experiments. In Paris, Professor E. J. Marey, about 1870, was investigating human and animal motion by means of various mechanical devices; he called the records chronographs. An American racehorse owner, Governor Leland Stanford of California, doubted the results of some of his investigations into the action of racehorses—in particular that there was ever an instant when a trotting horse had all its feet off the ground at the same time. E. J. Muybridge, an English photographer living in San Francisco, was commissioned to check Marey's findings.

In 1877 Muybridge succeeded in proving that Marey was right, and in doing so produced what were the first true chronophotographs. These classic pictures were made by arranging for a horse and rider to pass in front of a row of cameras with shutter releases connected to threads stretched at regular intervals across the path. As the horse came opposite each camera in turn, it broke the thread operating that particular shutter and took its own photograph. The series of photographs, when printed on one sheet, yielded a continuous chronophotograph.

CC-0. Agamnigam Digital Preservation Foundation - Chennai and eGangotri

In 1880 Muybridge devised a projection instrument which he called zoopraxiscope to demonstrate the movement. In 1884–5 he extended his chronophotography to the movement of a great variety of animals and human beings. In this series he used up to 36 cameras with shutters electrically operated by a clockwork device.

Marey's Single Negative. Muybridge's experiments prompted Professor Marey to adopt the photographic approach to his own researches. He constructed various cameras with this end in view, aiming at getting the whole series of chronophotographs on the one negative. His first apparatus, constructed in 1882, consisted of a plate camera equipped with a spring motor-driven rotary disc shutter having a number of regularly spaced apertures. As each aperture passed in front of the plate it recorded the position at that instant of an object moving across the field of the camera. A small object moving quickly recorded a series of separate images on the plate, the space between depending on how fast the shutter was rotated.

If the subject was large in relation to the speed of rotation of the shutter, the successive images overlapped and gave a confused picture. Marey overcame this difficulty by putting his subject into a black suit with a white stripe sewn down the arm and leg facing the camera. He then took the photographs against a black background and obtained a series of separate images of the white stripes. In this way he was able to produce records of the movements of the limbs of people walking or running past the camera.

Marey's next development was a "gun" which took a series of pictures of a moving subject and recorded them separately on a single plate. The gun carried a circular plate in front of which was a disc with twelve openings around its circumference. In front of this disc was a second disc pierced with a slit. On pressing the trigger of the gun, a clockwork mechanism rotated the discs. The disc carrying the twelve frames rotated one-twelfth of a revolution while the disc carrying the shutter slit revolved once, so that each of the twelve openings appeared in turn behind the lens and was exposed through the slit. The result was a plate carrying twelve separate photographs showing successive attitudes of the moving subject. This gun successfully recorded chronophotographs of birds in flight, taking twelve successive pictures per second with a shutter speed of 1/720 second.

MUYBRIDGE'S CHRONOPHOTOGRAPHIC SET-UP. A series of cameras were lined up along the track used to photograph the movement. The shutter release of each was linked to a rubber band held tensioned by a trip wire. As the horse moved over the track, it broke the trip wires which released the rubber bands and exposed a picture in each camera in turn.

In 1883 the French Government established a department of physiological research in Paris where Marey carried on a chronophotographic investigation of the movements used by humans and animals in various forms of activity. Marey subsequently recorded chronophotographic sequences on long rolls of paper and, finally, roll film and in 1892 was able to project them.

All of his instruments for this suffered from an inherent disadvantage: the sensitized material had to be transported fast enough to separate the images and brought to a sudden stop at each instant of exposure. In practice this meant being satisfied with very small images to reduce the amount of shift of the material between each exposure. But this type of record is only useful if the individual pictures are large enough to be examined in detail, and the sensitized materials of the time would not permit a high degree of enlargement. For this reason a number of workers in this field chose to develop the Muybridge approach of making the successive exposures in a number of separate cameras.

Other Systems. The apparatus used by General Lebert in 1890 consisted of six full-size cameras mounted in a circle with an electric motor in the centre. The motor carried an arm which rotated and operated the shutters of each camera in turn. This arrangement was used for photographing projectiles.

A year or two after this, Albert Londe constructed a camera in which sets of lenses equipped with electro-magnetic shutters formed separate images regularly arranged to occupy a single plate. One six-lens camera used a 13 × 18 cm. plate while one with twelve lenses covered a 24 × 30 cm. plate. With these cameras there was a separate clockwork selector switch, governed by a metronome which operated each of the shutter solenoids in turn, allowing a variable time interval between the successive exposures according to the speed and range of the action to be analysed.

In the mid-eighties, O. Anschütz, working on similar lines to Muybridge, constructed and used chronophotographic arrangements of up to twenty cameras. Like Muybridge, he devised a method of reproducing the movement from his results. He mounted his pictures on a drum which could be rotated to bring each picture in turn into a viewing aperture. As each picture came into view, it was illuminated by an electric spark so that as the drum rotated the observer saw a moving picture.

Present-day Use. Various workers in other countries were also interested in synthesizing movement in this way by means of chrono-

photographs, but, although chronophotography was directly responsible for the development of cinematography, it pursued its own distinct course right up to the present time. There is a basic difference between the two. In both a series of still pictures is taken of a moving subject. But the object of chronophotography is to present a series of still pictures for detailed study, each picture "freezing" a particular phase of the action. In cinematography the object is to produce a moving picture of the whole event.

So the still pictures taken in chronophotography are usually of a larger format and of a higher standard of definition than cinematograph pictures.

Today the most important application of chronophotography is in time and motion study.

A special type of chronophotography which is reminiscent of Marey's early apparatus is carried out today with electronic flash. The subject moves against a dark background and is illuminated by an intermittent flash while the camera shutter is left open. This produces a succession of images on the same plate, each image being displaced both in time and space from the preceding one by an amount that depends on the frequency of the flashes and the speed of the movement.

The method has both scientific and artistic applications. Because of the high speed of the flash, it is possible to analyse extremely rapid motion, while the movements of a dancer or athlete photographed in this way can produce interesting and even beautiful patterns. F.P.

CHRYSOIDIN. Diaminoazobenzene. Orange dye used in some desensitizers and dye toners.

Formula and molecular weight: $C_6H_5N_2C_6H_3(NH_2)_2$; 212.

Characteristics: Orange powder, stains fabrics and mordanted gelatin.

Solubility: Slightly soluble in water at room temperature.

CHURCHES. The technique of photographing churches is a normal aspect of architectural photography. Other specific considerations which may arise involve matters of perspective and its correction by camera movements.

In addition to such technical problems, the photographer may also have to consider non-photographic aspects, e.g., permission to take photographs in the church, which must always be sought beforehand; and in the case of weddings, familiarity with the procedure of the wedding ceremony.

C.I.E. STANDARDS. Standards of illuminants and of colour perception set up by the Commission Internationale d'Éclairage (International Commission of Illumination) to provide a means of accurately describing colours. Also known as I.C.I. standards or (in Germany) I.B.K. standards.

See also: *Colour measurement.*

CINE CAMERA

The basic elements of a cine camera are similar to those of a still camera: a lens, a light-tight compartment containing the sensitive film on which the lens projects its image, and a device (shutter) for opening and closing the light path through the lens to the film while exposing the picture for a specific length of time. Unlike a still camera, a cine camera must expose a series of images, one after the other, at a steady rate on a long strip of film.

An important part of the cine camera is therefore the film transport system. This, together with the necessary motor and film supply (usually amounting to something like 4,000 exposures per load) takes up an appreciable amount of space, so that a cine camera is invariably far larger in relation to its image size than a still camera.

Nearly always the pictures on the film are below each other, so that the film runs vertically through the camera, or at least the film gate (the part where the image is projected on to the film). Suggestions have been made for running the film horizontally and recording images side by side, but—with one short-lived exception—never realized in practice for amateur cameras.

In addition to the lens, film gate, film transport system and film supply, a cine camera must

also have a viewfinder, usually some means of adjusting the sharpness of the image, and provision for checking how much of the film load has passed through during shooting. Additional features may include adjustable running speeds, zoom lenses, a variable shutter, built-in exposure control, and other refinements.

Obviously the degree of complexity is related to the price of the camera and the more elaborate features are found on high-precision amateur and on professional cine cameras.

AMATEUR CAMERAS

Cine cameras for the amateur invariably use narrow gauge (i.e. narrower than 35 mm.) film. The most popular gauge is 8 mm. which is usually loaded into the camera in a 16 mm. width. As the film runs through the camera it is exposed along one half only, after which the film is turned over and run through the camera a second time to expose the other half. After processing the film is slit down the middle to produce two 8 mm. widths.

Charges containing a single 8 mm. wide film are used in quick loading cameras (Super-8).

A second amateur gauge is 16 mm., giving larger individual images (frames). The 9·5 mm. gauge is a third amateur size though less popular nowadays.

Lenses. The main difference between a still camera lens and a normal cine camera lens is that the latter has a shorter focal length because of the smaller picture size. This gives it an advantage over the still camera—a much greater depth of field. A fixed focus lens with a maximum aperture as large as *f*2·8 is therefore a very practical proposition with narrow gauge cine cameras. However, for serious work greater freedom is needed and, because the distance between camera and subjects will vary from a matter of inches to infinity, the lens is made to focus by means of an adjustable mount in which the lens moves bodily away from and towards the film in the gate.

The angle of view of a standard cine camera lens is, however, considerably narrower than that of a standard still camera lens. With the latter the normal focal length is taken as equal to the diagonal of the image format, giving a horizontal angle of view between 40 and 50 degrees. With a cine camera the standard focal length is usually about twice the frame diagonal, and the horizontal angle of view is 20 to 25 degrees.

Part of the reason for this is that as the cine camera records movement, it can concentrate on a smaller subject field and cover a wider field of view by swinging across it, much like the eye scans a scene it views, rather than taking it in all at once. (The eye does not take in the whole of a still picture at once either, but roams over the image area under normal viewing conditions).

The maximum aperture (effective speed) of a standard amateur cine lens is usually around *f*1·8. Only the very cheapest cameras have slower lenses, and frequently better cine cameras have lenses of maximum apertures of *f*1·4 and in exceptional cases as large as *f*0·95.

Few cine cameras are restricted to having only one lens. With many cameras, lenses of various focal lengths are available so that the cameraman may choose the one that best suits the circumstances of his shot: a wide-angle lens will be useful in cramped surroundings and a long-focus lens can secure a close view of distant action. The lens mounts are designed to make the range of lenses quickly interchangeable—in the less ambitious cameras by screw-in mounts where each lens must be unscrewed before the next can replace it; and in the more expensive equipment by an arrangement called a lens turret—a rotating fitment that usually holds two or three screw-in lenses, of which any one can be swung precisely into position with a minimum of delay.

Where the lens is fixed, afocal attachments can sometimes be fitted to convert the standard lens into a wide-angle or telephoto one.

On an 8 mm. camera the focal length of the standard lens is usually 12·5 to 13 mm. (½ inch), while wide-angle lenses range from 6·5 to 9 mm. in focal length. Long-focus lenses run from 19 mm. (1½ times magnification) upwards; usual ones are 25, 38, and 50 mm. (the latter having an image magnification of 4 times compared with the standard lens), or even longer. The standard focal length for a 16 mm. camera is 25 mm.; wide-angle lenses range from 13 to 17 mm. and long-focus lenses up to 75 mm. (3 times magnification) or longer for special purposes. The focal lengths for 9·5 mm. cameras are similar.

Lens mounts are frequently standardized with an internationally agreed lens thread and distance between the lens flange and the film. There are two such standards: the type C mount for 16 mm. cameras and the type D mount for 8 mm. models.

The type C mount for 16 mm. cameras has a diameter of 25·4 mm. (1 in.) with 32 threads per in. and a flange-to-film distance of 17·5 mm. 0·69 in.). The type D mount for 8 mm. cameras has a diameter of 15·8 mm. (0·632 in.), with 32 threads per in. and a distance of 12·3 mm. (0·484 in.) from the lens flange to the film.

A type D lens will thus fit any 8 mm. camera with a type D mount, so that the serious amateur with this type of camera has a very wide range of lenses to choose from. A number of cameras however have other lens mount standards or mounts suitable only for the lens range made by the camera manufacturer.

Lenses with a type C mount can often be fitted to cameras with a type D mount with the aid of an adaptor. The reverse is not normally possible, partly because lenses designed for 8 mm. cameras do not have a sufficient angular coverage in the larger 16 mm. field, and partly because there is no way of recessing the lens into the camera mount.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Zoom Lenses. Most modern amateur cameras, especially in the 8 mm. gauge, are fitted with a zoom lens. This has a variable focal length which can be adjusted even during filming, so altering the field of view and the image scale. It is thus possible to simulate a tracking shot—i.e. where the camera appears to approach or recede from the subject—by just working the focal length adjustment without moving the camera.

Zoom lenses are more complex in design and larger in size than units of any one of the single focal length covered by the zooming range. On the other hand the immense convenience of zooming and the fact that one lens covers a range of focal length greatly outweighs the possible drawback of bulk.

The zooming range of the lens depends largely on its price. Inexpensive zoom lenses for 8 mm. cameras have a range of 3 to 1 (for example 9 to 27 or 10 to 30 mm.), covering a medium wide-angle view to tele shots with a magnification of over 2 times. More expensive zoom lenses may have a range of 1 to 4 or even 1 to 6 (for example 8 to 48 mm.). For hand-held shooting it is generally preferable to choose a zoom lens with the widest possible angle at the near zooming limit, even at the expense of the lower tele-magnification. Where the latter is high, hand-held shots risk camera shake and hence blurring.

On 16 mm. and 9·5 mm. cameras the zooming range typically covers focal lengths from 17 to 85 mm., though extreme-range zoom lenses (for example 12–120 mm.) exist for professional 16 mm. cameras.

Zoom lenses also exist as afocal attachments to fit in front of the standard camera lens. Further, there are also afocal attachments for zoom lenses to change the focal length range. For example, one such attachment may convert an 8 to 48 mm. lens to a range of 6·25 to 37·5 mm., giving more scope at the wide-angle end of the range at the expense of the longer focal lengths.

The zooming movement is normally controlled by a lever on the lens itself. This may be radial (protruding from the lens mount and swinging up and down at the side of the lens) or longitudinal (swinging backwards and forwards below the lens). Other ways of control include a knob on the camera body itself, and power zooming arrangements. In this case a spring or electric motor increases or decreases the focal length on pressing one of two buttons on the camera or on the lens.

Finders. Cine cameras nearly always have a direct vision optical finder. On simple models the finder is built into the camera above or to one side of the lens and shows the field of view taken in by the standard lens. Additional image frames may show the fields with alternative lenses. For more advanced cameras the viewfinder may itself be adjustable, showing different fields of view either by changing the magnification or by adjusting a series of masks. A control on the finder usually shows the focal length to which it is set. For zoom lenses the focal length adjustment of the finder may be coupled to the zooming movement of the lens.

THROUGH-THE-LENS FOCUSING FINDERS. **Left:** *Prism system for focusing film in gate from behind.* **Right:** *Reflecting shutter which intermittently deflects the beam into the finder.*

Many modern cameras have a through-the-lens reflex finder. Here part of the light going through the lens to the film is diverted into the finder system. This arrangement has two advantages: first, the finder automatically shows the correct field-of-view irrespective of the focal length of the lens used (especially useful with zoom lenses); and secondly, visual focusing of the image also becomes possible.

There are two kinds of reflex finder, utilizing either a reflecting shutter or a beam splitter. In the first case the shutter which rotates in front of the film carries a mirror surface, so that the light is diverted into the finder system whenever the shutter obscures the film gate. In this way no light is lost from the exposure point of view, but the image in the finder may flicker slightly. Also, if the shutter stops in a half-open position at the end of a shot, no image is visible in the finder. (On the other hand most cameras automatically interrupt the shooting cycle with the shutter closed.)

In a beam-splitter camera the lens system contains a partially silvered reflector (usually a split prism with a semi-reflecting surface) which diverts about 10 to 20 per cent of the light from the lens into the finder system. The image in this case is always visible and always steady. If the camera is fitted with a built-in exposure meter, this must be calibrated to allow for the loss of light involved. The same applies if a separate exposure meter is used.

Generally, reflecting shutters are more common in professional cine cameras, and beam splitters in amateur models where the beam splitter frequently forms part of the zoom lens. Where the latter is not a standard fixture on the camera, it may carry its own through-the-lens reflecting finder.

Focusing. The simplest amateur cine cameras have a fixed-focus lens set for a depth of field from about 5 feet to infinity. On most models however the lens is adjustable and focuses over

a range of distances by means of a helical focusing mount. The distances are set by a scale engraved on the lens mount. The focusing range may extend from infinity down to three feet, or in certain cases down to a few inches, as some lenses have an ultra-close focusing mount.

CC-0. Agamnigan Digital Prestvation Foundation Chandigarh

Where a through-the-lens reflex finder is fitted, direct visual focusing is often possible. Here a ground glass or grained screen may be fitted in the system to show the actual image sharpness on viewing through the eyepiece. Some cameras incorporate a split-image rangefinder of the optical wedge type, where the picture is seen split in two with the two halves displaced relatively to each other when the image is unsharp, fusing into one continuous picture when the lens is set for the correct distance.

Some cameras take a focusing attachment with a prism and magnifying lens that fit into the camera gate instead of the pressure pad. This is useful for ultra close-up work and for titling with the camera set up on a rigid support. The image is focused in the film plane with the camera open, and the attachment also shows the exact field of view taken in. Focusing takes place before shooting, as the camera can only be loaded with film afterwards.

The lenses of more advanced cine cameras carry a depth of field indicator. This may take the usual form of aperture index marks arranged symmetrically to both sides of the focusing index, or it may consist of coloured dots which become visible at different aperture settings and are coupled with the aperture adjustment. On zoom lenses the index lines of the depth-of-field indicator may be curves uncovered to varying degrees according to the focal length setting. The ends of the curves actually opposite the distance of scale at any focal length selected show the depth of field at that setting.

The Shutter. Nearly all cine cameras have a shutter which periodically covers and uncovers the film aperture. Its main purpose is to cover the film opening while the intermittent transport pulls down the film to bring the next frame into position in the gate. Usually the shutter consists of a rotating blade of semi-circular shape, with its axis at the centre of the semi-circle. The shutter runs in synchronism with the film transport, so that the film is steady in the gate while it is uncovered by the shutter.

At a normal camera speed for silent pictures (16 frames per second) the shutter rotates with 16 revolutions per second; at higher speeds the shutter must be speeded up accordingly. This takes place automatically, through the gearing of the shutter and the film movement.

The shutter opening—i.e. the phase of the rotation during which the film is uncovered—is usually 180°. The shutter thus exposes the film for half the cycle of its operation, so that at 16 frames a second the effective exposure per frame is about 1/32 second. Sometimes the shutter opening may be slightly greater or slightly less than 180°.

While the angle of the shutter is usually fixed on simple cameras, more advanced models may have a variable shutter adjusted by a control on the camera. This may cover a range of movement from fully open (180°) to fully closed. When the shutter is open at 90°, the effective exposure time per frame is thus only half of what it is with the 180° opening—around 1/60 second at 16 frames per second.

Such a variable shutter has two uses. First, it permits control of the exposure of the film without adjustment of the aperture, e.g. when a limited depth of field is desired in the scene, or when the light is so bright that the film would be over-exposed even at the smallest lens opening. Secondly, it permits trick effects such as fading in and out during shooting.

THROUGH-THE-LENS REFLEX FINDER. The finder system on many modern cine cameras—especially those with zoom lenses—sees the view through the camera lens. The light is diverted through either a beam splitter or a mirror shutter and a part of it may be further diverted to an exposure meter system. A, eyepiece lenses. B, exposure meter mechanism. C, meter needle. D, cross-hair in finder. E, prism system with semi-reflecting surface to divert light to the photo electric cell F. G, field lens. H, mirror shutter (or beam splitter). FILM TRANSPORT AND SHUTTER. Top left: *Frame A in gate, shutter open.* Top right: *Claw engages film perforation as shutter closes.* Bottom left: *Shutter covers gate as claw pulls down film.* Bottom right: *Shutter uncovers film with frame B in gate as claw withdraws from perforation.*

An alternative shutter design uses an oscillating instead of a rotating system; this may have certain constructional advantages.

The shutter can also serve other purposes. Some cine cameras have shutter blades designed as a reflecting mirror which diverts the light into a through-the-lens reflex finder during the closed phase of the shutter. Systems have also been suggested where the shutter blades carry a barrier layer of a photo-electric cell, for direct exposure measurements through the lens.

The Film Gate. The gate is the position in the camera where the film is held during the exposure period. It is constructed in two parts, one fixed and the other (the pressure plate) free to move aside to allow the film to be loaded and held between the two parts in the correct focal plane.

The pressure plate is spring-loaded and the film rides through the gate channel on raised edges which hold the picture area of the film out of contact with the gate and prevent the film surface from being scratched. Gates of the best designs open very wide or are removable from the camera to allow easy cleaning. The fixed part of the gate has an aperture in it to suit the size and shape of the picture, but with most cameras an aperture in the pressure plate is not considered necessary unless required for through-the-lens focusing.

In the camera, the film is always run through with its sensitive emulsion (dull) surface facing the lens and the subject. The only exceptions have been some types of now obsolete colour films.

As a rule the gate aperture is fixed corresponding to the frame dimensions on the film as laid down by international standards. A few cine cameras have also appeared with a variable gate aperture, where masks can reduce the image height from the full frame height to virtually nothing. This can be used either for an additional way of fading in and out (a kind of wipe-fade) and also for producing wide-screen images with the gate in an approximately half-open position. The frame area on the film then has an aspect ratio of about 1·5 to 2 and the picture yields a wide-screen effect when the film is projected on to a screen of appropriate dimensions with a wide-angle lens in the projector. This, however, requires a greater image magnification, and part of the film area is wasted. If the film gate is varied during shooting, possibly in conjunction with the zooming movement of the lens, certain dynamic screen effects can be obtained; larger views for close ups and smaller ones for more distant shots, etc.

Intermittent Feed. The film is pulled down through the gate by means of a metal pin or claw that works as near the aperture as possible. There are various devices for driving the claw to save wear on the film. Ideally the movement of the claw should describe a narrow vertical rectangle: a stroke to pull down the film, a horizontal movement to withdraw from the sprocket holes in the film, an upstroke to return the claw to the top and a horizontal movement to engage in the sprocket holes again.

While the claw is the commonest film transport mechanism, especially in amateur cine cameras, various other systems exist. Best known is the Maltese Cross where a constantly rotating shaft imparts an intermittent movement to a sprocket wheel which is permanently in contact with the film. The sprocket thus pulls down the film through the picture gate in jerks. The Maltese Cross movement is more popular in professional cine cameras, especially the 35 mm. size where the film is larger and heavier and where, therefore, the claw may more easily damage the perforations.

Simple amateur cameras, especially the 8 mm. gauge, have only a single filming speed of 16 frames per second. More advanced models may have a range of speed, e.g. 8, 12, 16, 24, 32, 48, 64, and possibly even 128 frames per second. (Most common is a range of 12 to 32 frames per second.) In addition most cameras have provision for single frame exposures, when pressing the release button exposes just one frame. This is useful for certain tricks, animation and titling.

On some models the speed can be changed during shooting, for instance from 16 to 32 frames per second for instant switching over to

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

slow motion. Where the camera has a built-in exposure control system, this must be coupled with the change-over to keep the exposure of the film correct.

When cameras are intended for high speed work, the design of the intermittent mechanism becomes much more critical because vibration must be avoided from the rapidly oscillating parts. For speeds up to ten times normal (240 f.p.s.) the intermittently fed film is generally preferred because of the superior photographic results. But there is in any case a limit to the speeds attainable, governed by film strength.

Cameras running at higher speeds than 240 f.p.s. dispense with the intermittent motion and make use of a system of optical compensation to keep the image still in relation to the film; in effect, the film runs continuously and the image is caused to follow its movement at precisely the same speed. This principle is also used in some forms of viewer for editing.

For still higher speeds, systems have been devised of which many do not produce on the film separate images that can be projected but simply record data to be studied. Such systems are capable of an equivalent rate of exposure as high as 10 million f.p.s.

Camera Motors. The two most common drives for narrow gauge film cameras are the governor-controlled clockwork motor and the battery-powered electric motor. In either case the motor should ideally start instantly, though often the first frame or two of a scene may be over-exposed while the motor accelerated to its normal running speed.

Spring motors are wound by a key or a crank in the camera side. To prevent over-winding some cameras have a slipping clutch which comes into operation when the motor is fully wound. At one winding, the spring motor should be able to pull through at least 6 feet of film; on more modern cameras the capacity may be as much as 10 or 12 feet. The better cameras also have a device for stopping the motor automatically when it slows down near the end of the spring tension. That keeps the running speed constant. During filming, it is always advisable to rewind the motor after every scene.

Some cameras have the spring motor contained in a separate grip or handle; twisting the grip winds the motor.

Electric motors may be powered by a variety of batteries—dry cells or rechargeable miniature accumulators. Usually one set of batteries or one charge is sufficient for running about half-a-dozen films through the camera.

The advantage of the electric motor is, of course, that it eliminates rewinding and permits the shooting of longer scenes. Some cameras with a spring motor can also take an electric motor which attaches to a suitable driving shaft. Battery-powered cameras often have an indicator which shows the state of the battery to warn when it needs replacement or recharging.

The release button on the camera front or in the camera side starts the motor running for filming. Often, the button incorporates a continuous running lock, so that the camera can be set-up on a tripod and started while a cameraman walks into his own shot.

Many cameras are fitted with, or take, a pistol grip which incorporates the release button linked to the camera release. In addition, the starting button may be operated by a cable release. This can also permit remote control operations.

On electrically-driven cameras, remote control is easier, since it only involves plugging a cable with a switch into a suitable outlet on the camera body. On some models the batteries are contained in a handle or pistol grip; this may be removed and connected to the camera by a cable for remote operation.

More advanced amateur cameras may have a backwinding feature, usually by means of a separate handle which engages the motor shaft. This permits rewinding the film for double exposures—e.g. when making dissolves. If the camera is spring-driven, the backwind should only be used when the spring motor is partly run down, since it rewinds the motor at the same time as it transports the film in reverse. With electrically-driven cameras this problem does not arise and some models permit running the motor backwards over longer film lengths. For the most accurate results when making dissolves and other tricks in the camera, the rewinding should be done in conjunction with a good film measuring device—preferably a frame counter.

Footage Counter. All cameras have some means of indicating how much film has been exposed. Some of the dials work in jumps of so many feet, but the better ones move smoothly and may allow an estimate to the nearest 3 ins. of film, which is good enough for most purposes. An additional dial that is needed for the most accurate work is a frame counter by means of which any frame on the film in the camera can be found.

Some of the footage counters are self-setting to zero when the camera is loaded. A further convenient arrangement is one whereby the footage counter is visible in the viewfinder and can be watched during filming.

Exposure Control. On simple cine cameras with a fixed shutter opening and a single running speed, the exposure time per frame is also fixed and the lens aperture is the only means of controlling the exposure. The lens thus carries an adjustable diaphragm which may be in the form of an iris or—on simpler cameras—a pair of diaphragm plates with slots of varying width which reduce the effective opening as the plates move relative to each other. On some cameras the iris can close down fully and is used for fading a scene out or in at the end or beginning, respectively, of a shot.

Variable filming speeds and variable shutter

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

openings provide further means of exposure control. Generally the exposure time is inversely proportional to the camera speed: the exposure per frame at 32 frames per second is half as long as at 16 frames per second. While filming at different speeds the aperture must be adjusted to compensate; the variable shutter opening however is a means of deliberate exposure control when the aperture adjustment is inadequate or undesirable (e.g. for reasons of depth of field).

The correct exposure—i.e. usually the aperture setting—can be obtained from exposure tables or guides supplied with the camera or with the film. Some cameras have an exposure calculator with symbolic indications of different weather and subject conditions.

The majority of modern amateur cine cameras have, however, some form of built-in exposure meter.

ELECTRIC EYE SYSTEMS: Top: Conventional electric eye system. The light falling on the exposure meter cell controls the current flowing through the moving coil instrument which in turn works the diaphragm plates to set a larger or smaller aperture. A diaphragm in front of the meter cell adjusts the sensitivity to allow for different camera speeds and film speeds. Bottom: Self-compensating system. The meter cell measures the light, deflected by a mirror shutter, after it has passed through the lens diaphragm. The moving coil instrument is connected to the cell through a bridge circuit The diaphragm opens or closes to ensure that a standard light intensity reaches the meter cell. Errors in diaphragm calibration are automatically compensated. Camera speed and film speed settings are allowed for by adjustment of the bridge circuit. A, camera lens. B, diaphragm plates. C, moving coil instrument. D, battery. E, cadmium sulphide cell. F, shutter. G, film gate. H, film.

In its simplest form this may be a straightforward exposure meter which indicates the correct aperture value at a specified film speed and camera running speed. This value is then simply transferred to the camera controls. Slightly more elaborate are coupled exposure meters, where a meter needle is visible in the finder and lined up with an index mark by adjusting the lens aperture control. The latter is thus coupled with the meter system and directly sets the correct exposure.

Electric Eye Systems. The most popular exposure control system in cine cameras is the fully automatic arrangement where the exposure meter directly sets the lens aperture. This is usually implied when a camera is specified as having electric eye exposure control. There are several types, and they may use either selenium or cadmium sulphide cells.

In the commonest system the current from the photo-electric cell passes through a pair of coils which control the movement of two slotted aperture plates in the optical path. When little or no current passes, the plates are in their rest position with the wider ends of their slots overlapping, so that the lens is effectively at its full opening. As more current passes through the coils (due to more light falling on the cell) the aperture plates move so that the overlapping slots become narrower, reducing the lens opening. A pointer attached to one of the aperture plates may show the actual aperture set in the viewfinder, or may merely appear in the finder when the light is inadequate for a correctly exposed shot. The aperture is adjusted continuously, even during shooting.

Alternatively, a servo motor may adjust the lens aperture according to the prevailing light. In one set-up the motor drives the lens iris as well as an iris diaphragm in front of the photo cell, until the cell current balances in a bridge circuit. More light means more cell current which has to be reduced by closing the iris in front of the cell and hence the iris in the lens. This system usually adjusts the lens aperture before the camera starts running, but can also work during shooting.

Some cine lenses, specially for cameras without exposure meter, have a built-in meter cell which controls the lens aperture in one of the ways described above.

Through-the-lens Measurement. For reflected-light exposure measurements the meter cell should ideally take in exactly the same view as the camera lens. This is comparatively easy if the camera has a single fixed lens, but becomes difficult with interchangeable lenses. In a number of cine cameras, therefore, the exposure meter measures the light coming through the lens. That compensates automatically for the different fields of view, for changes in the lens-to-film distance at extreme close-ups, and in one case even for variations in the calibration of the aperture. There are several systems.

The swing-in cell moves into the optical path

of the camera lens before shooting. The cell measures the average reflected light and the lens aperture can be adjusted semi-automatically or automatically. The cell then swings out of the optical path for shooting; hence no continuous monitoring of the exposure level is possible. Such a set-up also requires a certain minimum space between the lens and the film for the movement of the exposure meter.

In beam-splitter systems, part of the light diverted into a through-the-lens viewfinder is further diverted to the exposure meter cell. The latter can thus continuously adjust the lens aperture according to the changes in the prevailing light intensity. Since only a small proportion of the light coming through the lens is utilized for exposure measurement, this method requires a highly sensitive meter cell of the cadmium sulphide type.

In some cameras the meter cell measures some of the light reflected from a mirror shutter. The meter in this case needs appropriate calibration to allow for the fact that the light reaches the cell intermittently and not continuously. A number of designs also exist (mainly in the form of patent applications) where a photo-electric layer on the shutter blades themselves measures the light falling on them and adjusts the exposure.

Most advanced are automatic compensation systems. Here the photocell measures the light coming through the lens and through the aperture diaphragm, via a beam splitter or a reflecting shutter. The meter output is balanced against the control current in a bridge circuit or fed in opposition to this control current into the coil controlling the aperture plates. If the scene is bright, the light reaching the meter cell causes the aperture plates to close down until the light is reduced to a point when the cell current balances the control current in the meter circuit. If the light increases or decreases, the current through the meter cell automatically causes the diaphragm plates to open or close the aperture. As this arrangement measures the light intensity that reaches the film, it is independent of errors in the lens aperture through calibration or mechanical wear and tear.

Compensations and Override. The exposure meter of electric eye cameras also has to allow for other variables connected with exposure: the film speed, camera speed and shutter opening. On the simplest cine cameras, only the film speed is a variable and is allowed for by placing different sized masks in front of the meter cell. The range of film speed covered this way is usually limited over a 4 : 1 range.

More advanced cameras allow for the variable factors by an adjustable iris diaphragm in front of the meter cell or by adjusting a rheostat controlling the current in the meter circuit. On some cameras the compensation for different running speeds is automatic, especially where the camera permits switching over from normal to high framing speeds during a shot.

CC-0. Asamnigam. Digital Preservation Foundation, Chandigarh

Advanced exposure meter systems may have a control to disengage the automatic coupling. This permits the cameraman to set his own aperture irrespective of the indicated light conditions. Often a meter needle indicated the correct aperture even when the automatic exposure control is disengaged; this aperture has to be set on the lens by hand.

Film Loading. Cine cameras normally have a feed spool on which the film is loaded into the camera, and a take-up spool to accumulate the film as it runs through and is exposed. The feed spool is usually free to rotate on its own spindle. Sometimes a weak brake is included to prevent the spool over-running when the mechanism is stopped. The take-up spool is driven through a clutch, belt or other form of drive that allows some slip to compensate for the changing diameter of the coil of film as it builds up on the spool. Some cameras will also run in reverse and they then automatically apply the same type of slipping take-up drive to what is normally the feed spool.

The majority of narrow gauge cameras use daylight loading spools. The daylight spool is made of heavy gauge metal with accurate cheeks that fit snugly to the sides of the circular coil of film. The film itself has several feet of perforated protective leader at beginning and end; these wrap around the outside of the coil and protect it from light both before and after

WAYS OF LOADING FILM. Top: Spools. The film is threaded through the camera mechanism and runs from one spool to the other. Bottom left: 9·5 mm. or single 8 mm. charger. The whole film is inside a light-tight container. Bottom right: 16 mm. magazine incorporating transport mechanism. This couples with the camera motor on insertion into the camera.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

exposure. The light-tightness relies entirely on this arrangement, so the spool must be protected from light as much as possible when it is not in the camera. Once the film has started to run, the camera must not be opened until the entire length has been exposed—otherwise several feet of the film will be fogged in both feed and take-up spools.

As the threading of the film through the gate, sprocket and on to the take-up spool is usually a finicky business, camera designers have produced various ways of simplifying this. These are developed along two lines; automatic loading and magazines.

In automatic loading systems it is only necessary to insert the film spool in the camera and push the film into a slot. The mechanism then takes over, laces the film along the correct path and—on some cameras—even attaches it to the take-up spool.

Magazine loading is the oldest system. Here the film is preloaded into a light-tight magazine which is simply inserted in the camera. In some cases the magazine is designed as if it were the back half of the film gate; the claw is then ready to engage with the film without any further adjustment. Such magazines are used in many 9·5 mm. cameras as well as some 8 and 16 mm. models. On some 16 mm. magazines the intermittent mechanism is actually inside the magazine itself instead of in the camera. This makes for rapid exchange of films in loading. Occasionally the loop of film may protrude from the magazine and has to be inserted in the film path of the camera.

SPOOL-LOADING MAGAZINES. Certain double-8 mm. magazines can be loaded directly from standard double-8 mm. spools, and then inserted in the cine camera. This permits rapid film loading and changing over at the end of the first run. Some magazines (bottom) are used in cameras designed to take either the magazine or the standard double-8 mm. spool without magazine.

A modern type of 8 mm. magazine consists of a plastic or metal case which is loaded with a standard 8 mm. spool. Its advantage is that film loading can be carried out at leisure, and the magazine clipped into the camera when required. This again permits rapid film changing during shooting. A few 8 mm. cameras even provide a choice of spool or magazine loading.

A special point with 8 mm. cameras is the need for reloading the double-8 mm. film at the end of the first run through the camera, for exposure of the second half of the film. In a spool loading camera this involves re-threading in the same way as the original loading procedure; the take-up spool and even the film itself may carry a marking like "exposed first half" or "half exposed" to indicate that the film must run through the camera once again.

This re-running is also simplified by a film magazine. Since the film runs through the camera in its full width, removal of the magazine in the middle of a run fogs a number of frames on both sides of the film. (With 9·5 or 16 mm. cameras the magazine permits removal of the film in the middle of a full magazine load without interfering with already exposed portions.)

Some cameras have special provision for rapid switching over at the end of the first run of double 8 mm. film. There the whole film container may swivel round, complete with film gate and intermittent movement. In one system the whole camera may be turned upside down for the second run, the lens being moved over from opposite the first film track to the second film track.

The Super-8 system uses a 50 feet length of single width 8 mm. film in a rapid loading cassette. There none of the mid-film changeover problems arise.

PROFESSIONAL AND SOUND CAMERAS

Professional motion picture cameras are mainly used for newsreels, documentary and feature film production as well as for certain special scientific purposes. They are usually 16 mm. or 35 mm. models taking film loads up to 1,000 feet with various other special provisions. Constructionally a professional camera is designed for heavy-duty work and is accordingly more robust and more bulky.

More advanced types of 16 mm. camera tend to be more complex than those for 35 mm. film, which often have less provision for special effects such as fades, dissolves, and other tricks. This is because these effects are produced by optical printing methods on 35 mm. film; such facilities are not available to most narrow-gauge users, so the only alternative for those film makers is to obtain their effects in the camera.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

On the other hand, professional motion picture cameras are more versatile in a number of other respects such as the use of special accessories and attachments. Significantly, few professional cine cameras have built-in exposure automation; since the cameraman is invariably a highly trained technician, he prefers to measure his exposure by more accurate methods with a separate meter, rather than rely on electric eye systems which give an acceptable result most of the time but are unreliable in a certain percentage of cases.

Lenses. The focal lengths of 16 mm. professional camera lenses cover much the same range as for amateur models, but are more extensive. Thus long focus and tele lenses of much higher magnification are sometimes used. This is practical, since the professional cine cameraman almost invariably works with the camera mounted on a rigid support. Zoom lenses are also more versatile, and may cover a zooming range up to 10:1, e.g. with focal lengths from 12 to 120 mm.

For 35 mm. cameras, the standard focal length is 50 mm., with wide-angle units from 25 mm. upwards and extreme tele focal lengths as long as optical manufacturers can make them. (Lenses of 2,000 and even 3,000 mm. exist for 35 mm. cine use.) Zoom lenses are handy for newsreel and documentary work, but are less used in feature film production.

This is because in a scripted film it is easier to decide on exact camera positions and angles of view with lenses of fixed focal length, while tracking shots are often made by actual camera movement on a dolly.

In view of the longer focal length—and hence reduced depth of field—of lenses on 35 mm. cameras, actual focusing becomes more important. Visual focusing systems, including observation of the image in the film plane or on a ground glass screen, are frequently used. On studio film cameras the focusing adjustment is often the job of a separate operator known as the focus puller, who has to adjust the distance setting to keep the main subject in sharp focus while it moves toward or away from the camera.

Film Transport. While professional 16 mm. cameras may still employ a claw movement for intermittent film transport, this is usually more rugged than in an amateur camera. Maltese Cross transport movements are also used since they are more effective in advancing the rather heavier 35 mm. film at a constant speed.

In some 35 mm. cameras the film itself is lifted away from the gate to reduce friction as it slides down to the next position. The registration pin may hold the film accurately in place when it is stationary during exposure. This is essential for precise film location to permit accurate matching up of images for various optical printing effects and tricks.

The cameras used in motion picture studios—and often those used for making newsreels—are driven by constant speed electric motors and synchronized with the sound camera which records the sound track separately. Cameras used for location work are generally driven by "wild" motors powered from mobile batteries. Some are driven by clockwork. The speed of these cameras is not controlled as accurately as that of the studio cameras.

The shutter on professional cameras is often of the mirror type to provide a through-the-lens view of the exact field taken in on the film. Alternative systems for through-the-lens viewing may utilize prisms that swing into the optical path when the camera is not running. Beam splitters in the system itself are rare, mainly because this tends to limit the range of interchangeable lenses that can be used.

Magazines. As a professional motion picture camera often needs a considerable film reserve, the space for the film is comparatively bulky. On most 35 mm. cameras and many 16 mm. professional types the film is loaded in magazines mounted externally on the camera. The magazine reels may be driven by a belt or by gears. It is this magazine which also makes the professional cine camera so bulky.

Usual film capacities for 16 mm. cameras are 100 to 400 feet; magazines up to 1,000 feet, however, also exist. The full capacity of a 35 mm. studio camera is usually also 1,000 feet. The magazines are loaded from spools or with film on cores. The exact packing and loading method depends on the make of camera. When a film is on a spool with opaque flanges it can usually be loaded into the magazine in ordinary lighting; film on cores has to be loaded in the dark.

Sound Cameras. Where live sound is used in professional motion pictures (in other words sound recorded during the shooting of the picture) this is almost invariably recorded separately. The recording medium is nowadays commonly magnetic tape or magnetic film (perforated motion picture film stock coated with a magnetic oxide layer instead of a photographic emulsion). The cine camera itself usually has to be enclosed in a sound-proof housing—a so-called blimp—to prevent the motor noise of the camera from being picked up by the recording microphones.

The sound record is then transcribed on to an optical track by being recorded photographically on to a separate film, the latter edited together with the picture film, and the picture and sound track finally printed on to the same positive film to produce a release print carrying both the picture and the optical sound track.

In newsreel and documentary film cameras the sound is often recorded on tape in a separate tape recorder, coupled with the camera by electrical means to synchronize the speed of the two.

The sound may also be recorded directly on pre-striped film—sensitive motion picture stock carrying a magnetic stripe. In such single-system cameras the sound is recorded on the

film ahead of the picture, so the editing presents special problems. Single-system sound cameras are normally used for newsreel and television filming. If the picture is shot on 16 mm. negative film, the editing may be done on a positive print and the sound track re-recorded from the stripe of the negative, similarly edited in step.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Amateur Sound Cameras. Single-system 8 mm. sound cameras record the sound on a magnetic stripe on pre-striped film. The camera contains the magnetic sound heads and may be battery or mains operated. Again the recording of the sound on the film—with picture and sound separated by the standard interval—makes editing virtually impossible, especially when a reversal film is used in the camera.

Alternative amateur live recording systems use a tape recorder powered by and coupled to the camera. Some amateur 8 mm. cameras have a special outlet for connection to a matched tape machine. The latter starts running as soon as the camera does, recording the sound effects while shooting the picture. After editing the picture and the sound, the latter may be recorded on a strip applied to the film after processing.

L.A.M.

ACCESSORIES

The accessories for normal cine use are similar in many ways to those used in still photography. One way in which they can be different is that in cinematography some of them are required to be used in movement. For example, in still photography a polarizing filter is fitted to cut out a troublesome reflection. In cine work not only can the same purpose be served, but two polarizers may be rotated against each other during the filming of a scene and produce the gradual reduction in exposure needed to make a scene fade out, a requirement that cannot apply to snap-shotting.

Another difference is due to the fact that cinematography is inclined to be a more strenuous pursuit—and the cameras are usually heavier—so there is a need for heavier duty equipment.

The Cine Tripod. A steady tripod is almost an essential accessory in motion picture making. The head of the cine tripod is designed to allow the camera to be swung horizontally (panned) and pivoted vertically (tilted); this accessory is known as a pan-and-tilt head, and is fitted with a long operating arm so that camera movements will be steady and under the control of the cameraman.

As often as not the professional uses a head that is stabilized by an internal flywheel; he also uses a tripod head that is controlled in both directions by worm gears turned by two separate handles. The type of head more often used by narrow gauge workers has a simple form of adjustable friction control for both pan and tilt movements, restrained so that they cannot turn too freely. It is important that a tripod head is steady when being rotated very slowly—any tendency to stick or jerk is enough to condemn it.

Mobile Camera Supports. The cameraman must often be able to go on filming while the camera follows behind a moving subject. Or sometimes it may be necessary to move (or track) up to or away from a static subject. So there are several types of mobile camera supports used in the professional film studio. Most of them are wheeled platforms upon which the camera on its tripod can be mounted.

The dolly is a robust three or four-wheeled platform of this type. It is pushed about the set by hand and carries the cameraman and his equipment. The dolly provides for horizontal movements only.

The velocilator is a rather more elaborate form of dolly. It is driven by hand or by an electric motor and incorporates an electrically-driven raising and lowering gear for the camera and its operator. Power for the motors is supplied through a trailing mains cable.

The camera crane is a mobile structure that supports the entire camera crew and, if necessary, the director on a platform rigidly slung from the end of the long jib. Like the velocilator the crane is completely power-driven through a trailing cable and it gives the cameraman an almost unlimited choice of camera angle and movements.

Small Accessories. Gauging exposure is a fundamental need, as with still photography. To satisfy it there are the same instruments: the exposure calculators, the optical extinction meters, the photo-cell meters. In some cases meters are also issued as cine versions which quote only the simplified shutter speeds possible with a cine camera. Sometimes attachments are sold which enable the meter to read the incident light as well as the reflected light. Most professionals use the incident light method of exposure estimation.

Filters are used extensively by professionals. Amateurs do not bother with them as much as they should. Apart from the range of normal coloured filters, use is made of the various other types, such as graduated sky filters, and ultra-violet filters. Particularly useful are neutral density filters; these are grey filters that cut down the light by a definite amount without affecting the colour values: they are used to prevent over-exposure or to make a larger lens aperture necessary so that the depth of field is reduced. Polarizing filters also have special value in cinematography; they can be used for reducing unwanted reflections, darkening sky tones, and as continuously variable neutral density filters.

Supplementary lenses, diffusion attachments, lens hoods and other normal still photography accessories also have their important uses in cinematography.

Rangefinders can be fitted to narrow-gauge cameras, but they are not vital items as the

normal cine lens has such a great depth of field. Professionals do not need them because they are able to focus through the camera lens.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Reflectors are useful accessories for amateur and professional alike. They are light-surfaced boards which reflect light into the deep shadows that often occur on close-ups of people. A silvered surface will give a hard light and a matt white surface gives a soft light.

Special Accessories. In the field of special effects the accessory designer has great scope.

The most important item is the effects (or matte) box, which at its best is a comprehensive lens attachment designed to hold a wide range of accessories and ensure their accurate placing in relation to the camera and the tripod; a registration device guarantees its alignment with the optical axis of the camera. At the front of the box is a vertical plate with an accurately cut aperture that admits light from the subject area covered by the lens, and no more; because of this the effects box is an excellent lens hood.

The amateur's effects box has to be more comprehensive than the professional's because the amateur has to do most of his special effects in the camera. Into the front of the appliance can be fitted various masks to cut down the picture area so that it represents the views seen through binoculars, a telescope, a keyhole and so on; also the masks necessary for split-screen effects.

Into the body of the appliance and nearer the lens can be fitted such attachments as mirrors, prisms for reversing or inverting the scene, odd-shaped pieces of glass (from broken bottles) for distorting the image, cylindrical distortion lenses, and the combination of short-focus positive and negative lenses which when separated can put an image considerably out of focus.

There are other special accessories besides the effects box. One intended for the amateur is a reverse motion cradle, for use if the camera cannot be run backwards. The cradle is a stoutly constructed frame fitted between the tripod and the camera and able to hold the camera firmly upside down.

A more ambitious attachment is an animation unit by means of which the camera may be operated one frame at a time at the intervals chosen to suit the particular task in hand. Such units are often used in cartoon work. One version of the mechanism is a completely automatic time-lapse unit intended for long periods of single-frame filming: it will operate not only the camera, but the lights and the cover which cuts off daylight from the subject for the exposure periods. This may be used for periods running into weeks or more.

G.H.S. & J.C.

EFFECTS BOX. Top: *Full-scale effects box with front and rear mask slots. These will take all kinds of cut-out masks, fading glasses, diffusion attachments, etc. At the same time the effects box also acts as a lens hood.* Bottom: *Simpler effects box. This is more portable and permits hand-held filming. Filters fit into the rear slot which is closest to the lens.*

CINE FILM

Since the cine camera exposes a long succession of pictures on a strip of film to recreate the impression of movement on projection, cine film is invariably supplied in lengths from 25 feet upwards—sometimes up to 1,000 feet. It is wound on spools or cores and carries regular perforations by which the transport mechanism advances the film in the camera. Cine film is available in a number of different widths or gauges. Standard cine film is 35 mm. wide and used almost exclusively for professional motion picture work. Narrow gauge films are 16, 9.5 or 8 mm. wide and used to be called sub-standard film to distinguish them from the standard 35 mm. gauge. This term is now largely fallen into disuse. Wider gauges than 35 mm. also exist.

NARROW GAUGE FILM

Of the three film gauges in this group, 8 mm. film is the most widely used amateur film

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CINE FILM GAUGES. Approx. natural size. Top left: *35 mm. silent* Top right: *35 mm. sound.* Upper centre left: *16 mm. silent.* Upper centre right: *16 mm. sound.* Lower centre left: *9·5 mm. silent.* Lower centre right: *9·5 mm. sound.* Bottom left: *Double-run 8 mm.* Bottom right: *Super-8 mm.*

material. It carries 80 frames per foot of film, with an image size of 0·138 × 0·189 inch (3·51 × 4·80 mm.), the projected frame size being 0·129 × 0·172 inch (3·28 × 4·37 mm.). The film is usually supplied and exposed in the camera as double-8 film, 16 mm. wide, which is subsequently slit down the middle after processing (see below).

A second version, Super-8, is produced mainly as single-8 film in preloaded charges. The film uses smaller perforations and carries larger images—the size being 0·166 × 0·224 inch (4·22 × 5·58 mm.) recorded on the film, and 0·158 × 0·211 inch (4·01 × 5·36 mm.) as the projected image area. This film carries 72 frames per foot.

The 8 mm. film—especially with magnetic sound track—is also being used increasingly for educational and instructional purposes.

The 9·5 mm. gauge enjoys a limited popularity among amateurs, but is obsolescent. It carries 40 frames to the foot, the image size on the film being 0·276 × 0·346 ins. (7·0 × 8·8 mm.) and the projected image area 0·236 × 0·312 ins. (6·0 × 7·93 mm.).

The 16 mm. gauge originally started as an amateur film size, but is today more widespread for professional purposes. The film may carry perforations along both edges (silent film) or only along one edge (sound film). There are 40 frames to the foot and the image size on the film is 0·294 × 0·410 ins. (7·47 × 10·41 mm.), while the projected image area is 0·284 × 0·380 ins. (7·21 × 9·65 mm.).

Film Types. Narrow gauge cine films are available in several types, according to their use and the manner of processing. They are:—

(1) Negative films. These resemble normal negative film for still photography, and are processed in more or less the same manner. They serve for the production of release prints (positives) in any required number. The negative is never screened in a projector, and therefore is not liable to damage. Negative stock is used principally by professional and commercial studios and newsreel companies where several positives are required.

(2) Reversal films. These make up by far the largest proportion of amateur cine film materials, and are processed by reversal to yield a positive image directly on the actual film that was exposed in the camera. The running cost of reversal film is therefore lower than with negative film, but the reversal positive is the only one of its kind. If it should get damaged or worn by repeated projection, any duplicate made from it would show the same injury to the image. If additional copies are required, they have to be made by duplication before the original is used for projection; for few copies, they are made on reversal film.

(3) Positive film. This is used almost exclusively for making positive prints from negative films, or occasionally also for filming titles. The latter is the only use for amateur purposes, since printing negative cine films requires special apparatus.

(4) Colour films. These are almost invariably reversal films, although 16 mm. negative colour film has been made for professional filming. The characteristics of narrow gauge make. In the 8 mm. gauge a large majority of amateur cine films are nowadays shot in colour.

Non-sensitized cine film is also available for splicing purposes—e.g., as leaders. For convenience, this often has a yellow base.

Speed. Narrow-gauge cine materials fall into four general speed groups, three black-and-white and one colour.

(1) High-speed materials. These are rated between 200 and 400 A.S.A., are available as negative and as reversal emulsions, and are used for filming by poor or artificial light.

(2) Medium speed materials. These are rated between 80 and 160 A.S.A., are available in negative and in reversal emulsions, and are intended for all-round use where the extreme speed of high-speed materials is not required.

(3) Fine grain films. Intended mainly for outdoor shooting, these materials come in

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

speeds from 25 to 50 A.S.A. Again they are available both as reversal and as negative emulsions.

(4) Colour films. These range in speed from about 12 to 40 A.S.A.; the majority being between 16 and 25 A.S.A. Narrow-gauge colour cine films are nearly all reversal materials, and are available in daylight and artificial light type emulsions.

Special professional 16 mm. colour reversal films exist in speeds up to 160 A.S.A.

Grain and Resolving Power. As with negative materials for still photography, the grain of narrow gauge cine films tend to increase with increasing speed. In view of the considerably greater enlargement which takes place during projection, narrow gauge cine films must have a finer grain than ordinary film materials.

A point in favour of the cine film here is that as the pictures are projected at the rate of 16 or more frames per second, no image remains on the screen for long enough to make its grain structure really noticeable. In other words, the grain becomes partly (but not completely) hidden by the change of images. This effect, however, does not compensate for the loss of resolving power due to the grain of the film.

The effect of grain and resolving power is, of course, most important with the smallest narrow gauge size—i.e., 8 mm. For that reason, some manufacturers do not produce high-speed films in this size.

Colour Sensitivity. Most narrow gauge cine films—negative as well as reversal—are panchromatic—i.e., sensitive to all colours. Many, especially the high-speed types, have an increased sensitivity to red which makes them particularly suitable for artificial light work. The positive films are generally blue sensitive only, as colour sensitivity is not necessary when copying from a negative. Positive films can therefore be handled in the light of a comparatively bright safelight for processing.

Sizes and Packings. The type of packing depends on the size of the film.

16 mm. film is available on spools holding 50 or 100 feet. For certain cameras it is also available in 50 feet magazines which can be loaded in full daylight and changed at any time during the run. The film is perforated on each side, with one perforation each side per frame.

16 mm. sound film is perforated on one side only, the other side carrying the sound track. This type of film is only used for professional filming and is usually available on spools holding 100 or more feet.

9·5 mm. film is available in 30 feet chargers, or 50 feet magazines, as well as on 50 and 100 feet spools. The designs of chargers and magazines vary with the make of the camera. The film is perforated in the middle with a single perforation between each frame. The image area extends almost to the edges of the film.

9·5 mm. sound film is similar to ordinary 9·5 mm. film, but carries a sound track along one edge while the picture size is somewhat reduced.

9·5 mm. duplex film carries two perforations between each pair of frames and can be used either in the orthodox way, provided the camera and projector are suitably adapted to take the film, or else it may be run off horizontally in a special camera which exposes only one side of the film. After running through the camera once, the film is turned over to expose the other half and then processed. After processing the film is slit along the middle, and the two halves are joined end to end to yield a film of twice the original length.

8 mm. double run film is available in spools holding 25 or 50 feet or in chargers or magazines holding 25 feet. The film is exposed twice, running through the camera once to expose one half, and then again, after turning over, to expose the second half. After processing it is slit down along the middle and joined end to end to produce double the original length. 8 mm. double run is 16 mm. with twice the normal number of perforations.

TYPES OF NARROW-GAUGE CINE MATERIAL

Type	*Speed A.S.A.*	*DIN*	*Gauges (mm.)*	*Uses*
Negative Films (Panchromatic)				
High speed	200–400	24–27	16	Filming in poor lighting conditions and particularly in artificial light
Medium speed	80–160	20–23	16	All-round filming
Finegrain	25–50	15–18	16	All-round filming in good daylight
Reversal Films (Panchromatic)				
High speed	200–400	24–27		Filming in poor light and artificial light
Medium speed	80–160	20–23		All-round filming
Extra-fine grain	25–50	15–18		Filming in good daylight, yields specially fine-grain and is thus ideal for 8 mm.
Positive Films (Blue-sensitive)				
Positive release	–		16	Printing films shot on negative film

Super-8 mm. film is available in single-run 50 foot chargers for Super-8 cameras. Thirty-foot chargers of single-8 film also exist for a few older cameras.

Magnetic sound film in all three gauges carries a magnetic oxide layer, applied as a narrow strip either outside the perforations, or in place of the optical sound track on 16 mm. film. It may be applied before exposure or (more usually) after processing.

PROFESSIONAL FILM

Professional motion picture production was originally based exclusively on the use of

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

WINDING OF 16 mm. SINGLE PERFORATED FILM. There are two ways of spooling up the film, known as type A and type B winding, for camera feed spools. They differ in the disposition of the perforations; in both cases the film is wound emulsion in. Type B is more common; if this is spooled on to another spool, it becomes type A winding with respect to this second spool.

standard 35 mm. film stock. Today this is still the main film gauge, though 16 mm. film is used in documentary film production, and extra wide film—up to 75 mm.—in certain wide screen processes.

The 35 mm. gauge carries 16 frames to the foot with 4 performations per frame. The image size on the film is 0·629 × 0·866 ins. (16·0 × 22·0 mm.), the projected image area being 0·602 × 0·827 ins. (15·29 × 21·0 mm.) This applies to sound film which carries a sound track alongside the image. In order to preserve the 4 : 3 aspect ratio of the picture, there is appreciable space between individual frames.

In addition special film gauges are used for making narrow-gauge release prints. The most important is 32 mm. wide film, perforated with 16 mm. perforations. The film is used for making 16 mm. positives with or without sound track, being slit down after processing into two 16 mm. widths.

Film Types. Unlike most amateur film making, professional motion picture production mainly employs negative-positive processes. So there is a larger number of film types as well as actual emulsions available. They can be grouped as follows:

(1) Black-and-white camera films. All 35 mm. cine film for use in the camera is negative panchromatic stock with speeds between 40 and 400 ASA. The slow emulsions are intended for outdoor location shooting, background etc. Most studio shots are taken on medium speed film of 100 to 200 ASA. Materials of 400 ASA and over are mainly used for newsreel work and other occasions where filming has to take place in poor light conditions which are not under the cameraman's control.

Professional 16 mm. camera films are made in the same emulsions. In addition there are also 16 mm. reversal films, mainly (but not exclusively) for amateur use.

(2) Colour camera films. There are three main types: negative, standard reversal, and low-contrast reversal. Most 35 mm. colour film is negative stock. Usually reversal films are available only in 16 mm. widths.

Standard reversal films are used where only one copy is likely to be required—though duplication for additional copies is possible.

Low-contrast reversal colour film is intended for 16 mm. shooting where a number of release prints are needed. The film yields a low-contrast reversal positive which is easier to duplicate, but is not itself suitable for projection.

(3) Black-and-white printing films. These are intended for making the final release print, and are available in 35 mm., 16 mm., 32 mm. and special wide-screen gauges. 32 mm. film serves for simultaneous printing of two 16 mm. copies side by side the films being then slit down the middle. The printing film for printing from negatives is usually a fine grain positive film, non-colour sensitized, and of fairly high contrast.

Reversal duplicating film is a non-colour sensitized fine grain reversal material for making release positives from black-and-white reversal originals.

(4) Colour printing films. Positive colour film is used for printing the colour negative to produce release prints. It also serves for printing colour positives from internegative film. The positive material is available in 35 mm., as well as in 16 and 32 mm. widths for reduction printing from 35 mm. negatives.

Reversal colour copying film is used for making release prints from the low-contrast camera material.

(5) Intermediate printing films. These are materials used for making internegatives and intermediate duplicates from a master negative or print for subsequent production of release prints.

Duplicating positive film is a black-and-white material of extreme fine grain and fairly high contrast. It serves for making the master positive from the original negative exposed in the camera. Duplicating positive film is available in 16 mm., 32 mm., 35 mm. and wider sizes.

Duplicating negative film is a fine grain non-colour sensitized black-and-white film of low contrast to preserve the full gradation of the picture. This film produces the dupe negatives from the master positive and serves for the final stage of making release positives. The dupe negative carries the picture but not the sound track.

Duplicating reversal film is often used for making a dupe negative from the original master negative in one step. This eliminates the need for making a master positive when only a comparatively small number of release prints are needed. For large releases it is better to go via a master positive, this reduces the need for handling the master negative when further dupe negatives are required.

Interpositive colour film serves for making duplicate colour negatives from the original master colour negative. The colour negatives are printed from the interpositive onto internegative colour film.

Interregative colour film is a negative material

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

for making colour negatives from normal reversal colour film for subsequent production of release prints, and for dupe colour negatives from interpositive colour masters.

(6) Sound recording films. These are used for recording the sound track on film during shooting or—more usually nowadays—during transcription from magnetic tape. There are two types: low contrast for variable density sound recording, and high contrast for variable area recording. The sound recording films serve for making the optical master track, a negative derived from the master magnetic track. The optical master track is then printed together with the master negative or a dupe negative of the picture to produce the release print. This therefore contains both the optical sound track and the picture—this is the so-called married print.

(7) Special films are produced for oscillograph recording, infra-red cinematography, television recording etc. For instance a television film for photographing the display on the screen is normally orthochromatic with a maximum colour sensitivity corresponding to the emission of the fluorescent screen.

Sizes and Packings. 35 mm. camera films are packed in lengths of 100, 200, 400, or 100 feet on 2, 10, and 3 in. cores, according to the camera for which they are required. The film is wound emulsion in or emulsion out, again according to the camera.

16 mm. camera films are packed in lengths of 100 to 1000 feet, 100 and 200-foot lengths are available on daylight-loading metal spools or on spoolless cores of various diameters according to the camera requirement. Longer lengths are available only on spoolless cores. The film is wound emulsion in.

Single-perforated 16 mm. film exists in two windings, according to the side on which the perforations are located relative to the winding direction. The usual winding is the type B.

Duplicating, intermediate and printing films in 16, 32 and 35 mm. stock are supplied in 1000-foot lengths (sometimes up to 1200 feet) on spoolless cores—usually 2 ins. in diameter. Single-perforated 16 mm. film is again usually wound according to the type B system. Some 16 mm. positive films are also available in shorter lengths.

CINE FILM PROCESSING

While the processing principles for cine film do not differ from those for still film, the dimensions and the length of the motion picture stock pose certain handling problems. These have been solved by the provision of specialized and often automated equipment for the purpose—particularly for professional use.

Among black-and-white cine films the material for professional use in the camera is mainly negative stock, while the preferred amateur material is reversal film. The latter provides a finished film ready for projection. Since the processing of amateur reversal films (colour as well as black-and-white) is usually included in the price of the film, user-processing is very much rarer in amateur narrow-gauge film making than it is among amateur still photographers. With black-and-white film at any rate it is, however, sometimes useful to be able to process a short test length to check exposure conditions, or even to process a number of films when results are required in a hurry or to ensure maximum consistency in the processed strips.

Professional cinematographers in the vast majority of cases use negative films—both in the standard 35 mm. and the narrow-gauge 16 mm. size. Here processing is practically never included in the price of the film and therefore has to be carried out independently. Further, the processed film is not an end product, but requires copying on to a positive film (which is also processed again) to obtain final projection copies.

PROCESSING BY THE AMATEUR

There are a number of simple processing units available which largely overcome the main objection to home processing, i.e. the difficulty of handling the long lengths of film involved. The following types of equipment may be used:

(1) Scaled-up apron or spiral reel tanks.
(2) Drum-and-trough set-ups.
(3) Motorized horizontal spool-type tanks.
(4) Small motorized continuous processing machines.

Reel Tanks. Simple processing tanks for cine

SIMPLE TANK PROCESSING OUTFIT. This is basically similar to developing tanks used for miniature still film, but employs a spirial reel with the appropriate film capacity and usually a mechanical loading aid to facilitate handling of the film lengths in the dark. A, reel on winding bench. B, film guide. C, tank body. D, film spool.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

film are derived from normal daylight processing tanks for still 35 mm. and roll film, but with increased capacity for 25–100 feet of 16 mm. film. The 16 mm. width of course also covers double 8 mm. film which is slit down the middle after processing by special film slitters.

The tank consists of a reel of suitable size plus a light-tight plastic container with lid and openings for pouring the processing solutions.

There are two main kinds, apron tanks and spiral reel tanks..

The apron tank consists of a flexible transparent plastic apron strip with intermittent raised dimples down each edge. The film is wound on to a supporting disc interleaved with The apron strip. Lengths of apron up to 100 feet are available together with supporting discs.

The spiral reel tank works on the same principle as spiral reel type tanks for still films, with the film being carried in a groove spiralling in from the circumference to the centre.

When handling film lengths of 25 to 100 feet, loading the film into the tank by hand is obviously impractical. Loading aids provided for either type of tank usually consist of a holder for the film spool, a second one for the apron in the case of an apron tank, and a hand or motor driven spooling unit for the tank reel itself. With spiral reel tanks the film is guided into the centre of the reel, and the guide then follows the grooves as the film is laid into them while the reel turns. A similar (or the same) spooling unit unwinds the film from the reel after the complete processing sequence and spools it up on reels for projection. In the case of double 8 mm. film the film can pass through the slitting device before spooling up.

The processing reels are made of transparent plastic to facilitate a second exposure when processing reversal film.

As an alternative to processing in the tank,

FILM SLITTER. Double-8 mm. film is processed exactly like 16 mm., but then needs slitting along the middle. Top: A simple slitting set-up passes the film from the spool through a cutting roller for immediate winding up on 8 mm. projection reels. Bottom: The slitter consists of two stepped and interlocking steel rollers. As the film passes through it is sheared apart accurately along the centre.

CINE FILM PROCESSING DRUM. The cine film is wound up on the outside of the framework, neighbouring turns being kept apart by suitable separators.

ordinary bowls can be used. In this case processing must take place in the darkroom.

The film stays on the reel even for drying. Special dryers available for the purpose take the complete reel and blow cold or warm air through it for about 15–20 minutes.

Drum and Trough Units. Older types of processing unit use a rack shaped like a drum on which the film runs in a spiral path round the outside. The drum is mounted on a framework dipping into a tray which contains the processing solutions which are poured in and out in turn. Lamps can be arranged above the drum for the re-exposure during reversal processing. This arrangement is economical in solution quantities, but the film is more laborious to load and processing has to take place in the dark.

Motorized Spool Tanks. This type of unit consists of two main components: a head unit with the two spools and a tank container. The head unit carries the spools on two geared shafts which may be hand or motor driven. The film is wound up directly on one spool and the end fixed to the second spool. The whole unit is then mounted on the tank container, so that both spools dip into the solution.

During processing, movement of the hand crank or the motor continuously winds the film from one spool to the other and back again to provide constant movement of the film in the solution and to prevent the turns from sticking to each other. The reversal exposure may take place either by lifting the head unit out of the tank and continuing the spooling to and fro in front of a lamp, or by including a shuttered window in the side of the tank.

Several tank units may be provided to permit the head with the spools to be lifted from one solution to the next. Alternatively the solutions may be poured in and out of the one tank body in succession. For drying the film is wound on a drying drum.

Small-scale continuous processors work on the same principle as commercial cine film processing machines, with the film running over rollers through a succession of tanks. Such units are usually too costly for amateur cinemato-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

graphers and are designed mainly for use of laboratories, research groups etc.

Handling Films. Amateur cine films are usually of the reversal type and the processing sequence involves development to a negative, followed by removal of the negative image, re-exposure, and development of the remaining silver salt to a positive.

Processing negative films is simpler, but this type of material is less popular for amateur use. It only serves as the intermediate for obtaining a positive copy, which must normally be done by a professional laboratory.

Positive film is useful for making titles to be spliced into a picture on reversal film.

Black-and-White Reversal Film. The sequence of processing is as follows. In total darkness or by a deep green safelight:—

(1) Pre-soak the film for 2–3 minutes in water to ensure even development.

(2) First development to produce a negative image. A suitable formula is:—

Metol	35 grains	2 grams
Sodium sulphite, cryst. ...	7 ounces	180 grams
Hydroquinone	140 grains	8 grams
Sodium carbonate, cryst. ...	5 ounces	125 grams
Potassium thiocyanate ...	35 grains	2 grams
Water to make	40 ounces	1,000 c.cm.

Develop for 6 minutes at 65° F. (18° C.). This solution may be saved and used again for the second development.

(3) Hardening bath. This must be included in the process if the bleaching bath A, designed to prevent staining, is used. If preferred, bleach bath B may be used and the hardening bath omitted. The formula for the hardening bath is:—

Formalin (40 per cent) ...	1 ounce	25 c.cm.
Sodium hydroxide	27 grains	1·5 grams
Water to make	40 ounces	1,000 c.cm.

Harden for 5 minutes at 65° F. (18° C.).

(4) Rinse for 2 minutes in running water to remove the developer and hardener.

(5) Bleach in one of the following bleaching baths to dissolve away the negative image:—

PROCESSING DRUM SUPPORT. This carries the processing drum as well as the solution tank. Accessories on the support frame include a spool bar for easy loading from the camera take-up spool, and a perforated tube for spray washing of the film between the processing stages. The solutions are replaced by changing the tank (not shown). A, spool bar. B, support for tank. C, half-bearings to support the film drum. D, spray tube with hose to water supply.

RECIPROCATING DAYLIGHT PROCESSING TANK. The film is wound continuously from one spool to the other and back again, reversing automatically each time. The spools are mounted on shafts underneath the winding head which fits over the processing tank, making a light-tight seal. The winding can be by hand crank or a motor. The film only needs winding on to one reel and attaching to the second reel in the dark. A, water-tight winding head. B, film spools with film. C, tank.

Bleaching Bath A

Water	40 ounces	1,000 c.cm.
Potassium permanganate ...	35 grains	2 grams
Sulphuric acid (conc.) ...	192 minims	10 c.cm.
Silver nitrate (10 per cent)	77 minims	4 c.cm.

Bleach for 7 minutes at 65° F. (18° C.). This solution will not keep after use.

Bleaching Bath B

Water	40 ounces	1,000 c.cm.
Potassium bichromate ...	175 grains	10 grams
Sulphuric acid (conc.) ...	200 minims	10 c.cm.

Dissolve the bichromate in the water, then add the sulphuric acid slowly, and with constant stirring, to the cold solution. Bleach for 5 minutes at 65° F. (18° C.).

(6) Rinse in running water for 2 minutes.

(7) In an orange or bright green safelight: clear in the following clearing bath to remove the bleacher stains.

Sodium bisulphite	2 ounces	50 grams
Water to make	40 ounces	1,000 c.cm.

Clear for 2 minutes at 65° F. (18° C.).

(8) Rinse in running water for 1 minute.

(9) Second exposure, to make the remaining silver halide developable. The film should be exposed to the equivalent of 100 watts at 8 feet for 1 minute, whilst the drum is rotated very quickly to ensure even exposure.

(10) Second development to form the positive image. The developer used for the first development may be used again. Develop for 5 minutes at 65° F. (18° C.).

(11) Rinse in running water for 1 minute to remove the developer.

(12) Fix in this fixing bath:—

Sodium thiosulphate, cryst. ...	10 ounces	240 grams
Sodium sulphite, anhyd. ...	265 grains	15 grams
Glacial acetic acid	330 minims	17 c.cm.
Boric acid, cryst.	130 grains	7·5 grams
Potassium alum	265 grains	15 grams
Water to make	40 ounces	1,000 c.cm.

Fix for 10 minutes at 65°F. (18°C.).

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

In white light:

(13) Final wash. Wash in running water for 30 minutes.

(14) Drying. If a dryer is available to take the film on its developing reel, this is ideal. Otherwise a simple drying drum may be used. There are several types of drum on the market and they are effective in drying the long lengths of film without causing drying marks or impression marks.

The film must be absolutely dry before being re-spooled. While re-spooling, maintain an even tension, but never tighten the film already on the spool, as this may give rise to scratches.

Negative Film. Processing of negative film must be carried out in total darkness or by the light of a dark green safelight. The sequence is as follows:—

(1) Pre-soak for about 1 minute.

(2) Develop for a time found to be correct for the particular processing machine in use, by processing short tests on standard exposure subjects.

(3) Rinse for 1 minute.

(4) Fix for twice the time taken to clear. The white light may now be switched on.

(5) Wash for at least 30 minutes.

(6) Dry and spool up.

Positive Film. This is non colour-sensitive, and processing may be carried out by the light of an amber safelight. The sequence is:—

(1) Pre-soak for about 2 minutes.

(2) Develop in a contrast developer for a time indicated by a test film.

(3) Rinse for 5 minutes in running water.

(4) Fix for twice the time taken to clear the transparent sections.

(5) Thoroughly wash in running water for at least 30 minutes.

(6) Dry and spool up.

Colour Film. Most reversal colour films can be processed by the user in much the same way as black-and-white reversal films. Although the processing cost by a laboratory appointed by the film manufacturer (or by the manufacturer himself) are included in the purchase price of the film, home processing again has the advantage of making test exposures quickly available for evaluation. Some manufacturers publish formulae or market processing kits for reversal colour films; independent processing formulae have also been published from time to time.

Certain types of reversal colour film can only be processed by the maker or specially equipped processing laboratories, since the procedure is rather more complex.

Negative colour films are rare in narrow-gauge sizes. Where available, processing follows largely the same procedure as for negative black-and-white film. Temperature control is much more strict, and the maker's recommended chemicals should be used. The making of colour positives from colour negatives is beyond the scope of the amateur cinematographer, so that home processing even of colour negative cine film is rarely worthwhile.

Processing Tests for Black-and-White Film. Preliminary processing tests made on a film exposed on a test chart can provide useful information about the characteristics of the film, and the efficiency of the equipment.

The chart may include black and white discs on a white and black background respectively.

The black discs on the white background are a test for streakiness in development and, should this defect occur, the images of the discs will have trailing grey tails either above or below them. This trouble is known as directional effect. It occurs when solution agitation is poor and exhausted developer remains very near to the film surface.

In addition the chart should include a grey scale of areas ranging from white through the greys to jet black. This tone range checks the reversal process generally and, particularly, shows whether the second exposure covers the whole range between highlights and shadows.

The chart must be illuminated evenly for the test exposure. Expose about 20 feet of film, and then carefully store the chart for tests.

Preliminary tests of the processing solutions employed, to establish optimum times, etc., can also be made on short lengths of test film. For this purpose an ordinary roll or miniature film tank is ideal, if it is adjustable to take 16 mm. film widths. The test itself need involve only a foot or two of film. A series of tests can for instance be made, varying the first and second development times, and so on. When making such a series, change only one variable at a time.

With this arrangement quite small quantities of processing solution are adequate; the typical amounts for an adjustable roll film tank used for 16 mm. film would be around 250–300 c.cm.

Provided the times and temperatures for the preliminary test are carefully followed in the full scale processing routine, the differences between the two results will be so slight that the full film should be almost perfect.

Professional Cine Processing. Motion picture laboratories use partly or fully automated continuous processing machines. There the films run through the machine at a constant speed, running over rollers from tank to tank. In some machines the films do not even touch the rollers, but ride over a liquid or air cushion that keep it a fraction of an inch away from the roller itself.

The processing times at each stage are determined by the length of film running through any given tank. The longer the film path, with the film moving at a constant speed, the longer obviously the time of treatment. The solutions in the tanks are thermostatically controlled and automatically agitated.

After processing sequence the film runs through a drying chamber and is then spooled up on large reels.

Films from professional cine cameras are

usually several hundred feet in length (positive films from printers up to 1,000 feet), which shorter lengths are being processed, they are frequently spliced together for going through the machine continuously.

Professional motion picture film processing machines are also extensively automated, with controlled replenishment of solutions and automatic warning signals if a film should break.

CC-0. Anand Mitra Digital Preservation Foundation Chandigarh

Colour film processing largely follows along the same lines, with correspondingly bigger machines to accommodate the greater number of solutions required.

Some film processing machines use special systems of solution application, such as spray units, viscous solution applicators, and so on.

Books: *How to Process*, by L. Wheeler (London)

CINE HISTORY

The desire to produce a picture of the world around him has occupied man for many hundreds of years. Movement has played an important part in these attempts.

The earliest forms of artificially produced moving image took the form of shadows cast by a fire or lamp on to some sort of screen—the Chinese shadow plays are an example. With the invention of the magic lantern, a further advance was made with the use of articulated metal figures and painted transparencies which could be projected on a screen and given a semblance of motion. These slides, operated by levers or gears, were currently in use throughout the nineteenth century.

FUNDAMENTAL DEVELOPMENT

The motion picture is based on the phenomenon of persistence of vision—in which the eye retains the image of an object for a fraction of a second after the object is removed, an effect recognized since the days of Ptolemy. In December, 1824, P. M. Roget carried out the first experiments showing the principles behind this phenomenon. J. A. Paris introduced a toy—the Thaumatrope—in 1826 which, by the rapid rotation of a card held between two threads, enabled the eye to superimpose (by persistence of vision) the images on both faces at once—a bird and a cage, a horse and rider, and so on.

Early Animation Experiments. It was J. A. Plateau in 1829 who laid down the theory of persistence of vision. On the basis of this work, he invented in 1832 the Phenakistiscope—consisting of a circular card with a series of images drawn on its face, and a number of apertures around its circumference; when rotated on its axis and viewed through the apertures in a mirror, the drawings appeared to move.

Simultaneously, S. R. von Stampfer invented a very similar instrument, the Stroboscope, W. G. Horner in 1833 devised a cylindrical form, known by him as the Daedateum, popularized in later years as the Zoetrope. Miniature forms were made by Molteni and others for projection with the magic lantern, using glass image-bearing discs with rotating shutters on the same axis—the shutter rotating ten times for every rotation of the picture disc.

An important modification of this system was made by Molteni, and adapted by Beale in his Choreutoscope; instead of rotating continuously, the picture disc was moved intermittently by a form of Maltese cross mechanism, one picture for each revolution of the shutter; the efficiency of the system was thus greatly increased. This was the first use of an intermittent mechanism in the production of moving pictures.

In 1877 Emile Reynaud produced the Praxinoscope, a form of Zoetrope in which a cylindrical band of drawn images was viewed, not directly, but as a virtual image in a twelve-sided mirror drum in the centre of the cylinder. The results were of a very much higher quality than those of the conventional Zoetrope.

Reynaud patented in 1888 a projection Praxinoscope in which a transparent, flexible band with perforation holes was transported by a drum carrying pins engaging in the perforations; this formed the basis for his Théâtre Optique which gave public performances from 1892 until 1900, each film being drawn and coloured by Reynaud.

Photographic Experiments. Although photography had been an accomplished fact since the 1830's, it was not until after the invention of the wet collodion plate that instantaneous photography became possible. T. H. DuMont in 1861 and W. Donisthorpe in 1876 among others proposed means of exposing plates in rapid succession, the resulting negatives being printed for viewing in a Zoetrope.

Chronophotography—the use of instantaneous photographs taken at regular intervals for the study of movement—gave a tremendous impetus to the development of the motion picture. The first apparatus was made by Janssen, and called the astronomical revolver, being used to record the transit of Venus across the sun in 1874. Eadweard Muybridge, working in California, started a series of experiments in 1877 using a battery of cameras exposing in rapid succession. He thus obtained photographs of successive phases of horses in motion; these results could be viewed in a Zoetrope, or projected on a screen by his Zoopraxiscope (1880).

E. J. Marey, in France, constructed in 1882

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

the photographic gun, taking a circular plate on which 12 exposures were made successively by a rotating shutter, the plate being moved intermittently between exposures by a clock mechanism. It was used to describe the flight of birds. During the same period, A. Londe in France was working with a multiple lens apparatus and O. Anschütz in Germany used batteries of cameras similar to those of Muybridge.

Basic Improvements. Glass plates could be used to record only a few pictures at a time; the introduction of flexible films—at first paper rolls—overcame this difficulty. Marey in 1887 constructed the first practical cine camera which used rolls of light-sensitive paper. An intermittent mechanism carried the "film" through the camera, exposing it while stationary and covering it by a shutter while moving. Marey used the camera with great success in the study of animal movement.

By the end of 1887 the two principles of analysis and synthesis of movement had been thus demonstrated. It now remained for these principles to be exploited for commercial ends.

In the years between 1888 and 1893 a number of inventors in different countries tried to apply these principles, among them Le Prince (1888, Friese Greene and Evans (1889) and Donisthorpe (1889) in this country. None of them was able to solve successfully the mechanical problems involved in taking and projecting sequences of images. The first commercially successful apparatus was introduced in America by Thomas Edison, whose laboratory had developed, by the end of 1889, a working film camera which he called the Kinetograph. The camera had been made possible by the introduction of flexible celluloid films produced by George Eastman, and intended for use in the earliest box cameras. Edison cut these films down to 35 mm. width, and perforated the film with four pairs of rectangular perforations to each frame—essentially the same arrangement as in modern practice. Films taken with this apparatus were first shown to the public in 1893, in the form of coin-operated peepshow machines called Kinetoscopes. Edison had decided against projection, as a less lucrative form of presentation.

Public projection of movie films was first demonstrated by Louis and Auguste Lumiere, who, stimulated by the Kinetoscope, built the Cinematographe in 1895—a combined camera, printer and projector for 35 mm. film. The apparatus used a claw mechanism to move the film, and was light and portable. With it, the Lumieres gave the first of many public shows of projected moving pictures at the Grand Café in Paris, on December 28th, 1895.

Simultaneously with but independently from the Lumieres, Birt Acres and R. W. Paul in Great Britain, W. Latham, T. Armat and C. Jenkins in America, M. Skladanowsky in Germany and G. Demeny in France introduced workable apparatus, and by the end of 1896 cinematography was a recognized and profitable business.

As the industry grew, standardization became more and more essential; in 1909 an international conference decided to adopt the Edison perforation and film width as standard. It has remained so with minor modifications until the present day. The Maltese cross mechanism, operating intermittently a sprocket wheel below the gate, became employed almost universally in projector design, while a claw mechanism was used in cameras.

Detailed Improvements. There has been relatively little change in the mechanical principles of camera and projector design in recent years; in details the apparatus has been immensely improved, however. An important advance in camera design was the introduction of the registration pins which, inserted into perforations while the film is being exposed, result in a much more steady picture. The first British patent to cover the use of this device was issued to T. H. Blair in 1896.

Proceeding concurrently with the development of cameras and projectors has been the invention and elaboration of the ancillary apparatus: printers, processing machines, perforators, film stock—all of which, by their many improvements, have added to the high technical quality of modern film production.

Narrow-gauge Cinematography. The 35 mm. film width was adopted as a standard very early in the development of cinematography, but for reasons of economy or convenience a number of film widths narrower than this have been employed—principally for amateur use. One of the first to use narrow gauge film was the British pioneer, Birt Acres, who used in his Birtac camera 17·5 mm. film formed by splitting standard stock down the middle.

One of the earliest amateur cine cameras was the Biokam, 1899, which used 17·5 mm. stock with one perforation between each frame. Pathé introduced in 1912 the Pathé-KOK projector, hand operated with a built-in generator for illumination; this took 28 mm. film on a safety base, the films being reduction prints from Pathé 35 mm. productions.

Amateur cinematography can be said to have begun, however, in 1923: the Eastman Kodak Company produced the first 16 mm. reversal safety film, and Victor and Bell Howell introduced suitable cameras and projectors. In the same year Pathé introduced the 9·5 mm. gauge. Eastman Kodak introduced the 8 mm. film size in 1932; since then this gauge has overtaken 16 mm. and 9·5 mm. in popularity. Colour films have been available for some time in all three sizes; with the introduction of magnetic striping methods, 8 mm. and 16 mm. films can be easily provided with sound tracks.

Equipment for the production of stereoscopic and wide-screen films, including ana-

morphic lens systems, is available for amateur use.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Originally intended for amateur use, 16 mm. and 8 mm. films are used to an increasing extent by professional film producers for publicity, educational and propaganda films, while some films have been enlarged to 35 mm. for commercial distribution with great success.

SOUND AND CINEMATOGRAPHY

Sound has been associated with the motion picture from its beginning. Edison's aim was to produce motion pictures to accompany his phonograph, patented in 1877; it is claimed that the first successful experiment in his laboratories was made with a synchronized phonograph record. Many early pioneer workers included in their patents provision for use of phonographs—notably Demeny who, with his apparatus, patented in 1892, used to photograph and project facial movements as an aid to teaching the deaf.

Various methods for electrically or mechanically synchronizing phonograph records to motion pictures were patented in the years up to 1900; at the turn of the century, a number of short films of music-hall turns accompanied by phonograph records had been made—with some success. In 1911, Gaumont produced the Chronophone apparatus using synchronized discs, amplification of the records being carried out mechanically. This system was operated with great success for a number of years at the enormous Gaumont-Palace cinema in Paris.

Recording on Film. Eugene-Augustin Lauste was the first person to achieve any success with sound-on-film recording. A former associate of Edison, from 1900 he became interested in the problems of recording sound, and by 1904 had succeeded in recording sound and visual images on the same film. For the years preceding the first world war he worked at, and patented, many forms of light modulator, his success being limited only by the lack of means for amplifying the signal obtained from his film records. In principle, however, his work anticipated modern methods of optical sound recording.

The invention of the triode valve, with the electronic amplification subsequently possible, gave work on recording sound a fresh impetus. The firm Tri-Ergon, formed in Germany in 1919, produced a system employing a glow lamp which converted electrical variations from the microphone into brightness variations. In spite of an effective demonstration in 1922 in Berlin, the system was not adopted by any company.

At the same time Lee de Forest in the United States was carrying out experiments with a modulator lamp of his own design, and in collaboration with T. W. Case—who had developed a bismuth sulphide photoelectric cell—he demonstrated his Phonofilm sound system in 1923 at the Rivoli Theatre, New York. T. W. Case also devised a modulator lamp which he called the Aeo-Light; Fox acquired the right to his process in 1926 and created the Fox-Movietone system. C. Wente at the Bell Telephone Laboratories in 1922 invented an electromagnetic light valve—this became the basis of the variable density system exploited by Western Electric, who had also created a process using sound on disc known as Vitaphone.

General Adoption of Sound. In spite of these advances, no major film producer entered the field of sound films; only Warner Brothers in 1926 adopted the Vitaphone system for one and two reel vaudeville shorts and comedies.

In 1927 Fox-Case and Warner Brothers began a campaign in favour of the sound film. On the 23rd January, 1927, Warner Brothers launched *The Jazz Singer* starring Al Jolson, the first talking, singing feature film—while Fox-Case presented, in May 1927, their first sound feature *Seventh Heaven*.

A year later, R.C.A., with Westinghouse and the General Electric Company, announced their system of variable area sound recording. This was based on the Pallophotophone System, devised by C. A. Hoxie in 1920 and using the methods first demonstrated by Lauste in 1910.

Gaumont in France, in conjunction with the Danish engineers Petersen and Poulsen, adopted the G.P.P. system; this employed a separate 35 mm. sound record. They produced by this process *L'Eau de Nil* in 1928. The system was soon dropped owing to the difficulty of dealing with two film strips.

In Germany, the Tobis-Klangfilm organization was formed. There followed a severe battle with Western Electric and R.C.A. over Tri-Ergon patents, but the dispute was settled amicably in 1930.

The variable area and variable density methods soon became universally accepted; they were applied also to 16 mm., 9·5 mm. and to the now obsolete Pathé Rural 17·5 mm. substandard films. Improvements in sound quality came rapidly, in particular with the development by R.C.A. of push-pull variable area recording.

Recent Developments. A major innovation was introduced in 1941 with the stereophonic system employed for certain versions of Walt Disney's *Fantasia*. A separate 35 mm. sound recording film, run in synchronization with the visual record, carried a number of sound tracks each designed to operate individual loudspeakers in the auditorium. With the development of magnetic recording techniques, and the introduction of wide screen projection, the use of stereophonic magnetic sound tracks has now become a common practice.

The introduction of a system for applying a stripe of magnetic recording material to the edges of 35 mm. or substandard prints has

CC-0. Jammu and Kashmir Digital Preservation Foundation, Chandigarh

resulted in an improvement in versatility and quality of sound recording. In the case of substandard films in particular, this has made it possible to record synchronized commentaries and music with less cost and difficulty than in the case of optical sound.

COLOUR FILMS

The earliest colour motion pictures were made by hand-colouring each frame. This technique was usually carried out in small factories employing a number of girls, each of whom applied one colour. The method was used, often with great effect, from the earliest days of cinematography.

As the length of films and the number of prints increased, this became impractical, and Pathé devised a method of applying dyes through stencils made from positive prints; up to six stencils were used, one stencil for each colour required. Each positive stencil was run through a printing machine, in register with the positive film and the colours were applied through the stencil by means of rollers or brushes. This method, known as Pathecolour, was in use for many years and gave, for most subjects, very pleasing results. The idea, although elegant, was costly for long films, so simpler techniques were employed to give a coloured image—the principal methods being chemical toning and dye tinting, and combinations of the two methods.

Additive Processes. The above processes were, of course, non-photographic, and it was not until G. A. Smith, in 1906, filed his patent for a two-colour additive process that colour cinematography became a practical commercial proposition. Commercialized in 1910 as Kinemacolor, the process employed a camera taking successive frames through rotating red and blue-green filters at 32 frames per second (twice the normal speed); a projector with a rotating filter disc similar in principle to the camera was used for showing the film. The results were, for many subjects, very pleasing, though they suffered from colour fringing in the projected images.

Subsequently, many processes were marketed employing successive or simultaneous admixtures of two or three colours. Examples of the more successful additive processes were the Keller-Dorian-Berthon lenticular process—marketed in 16 mm. by the Eastman Kodak Company as Kodacolor from 1928 to 1935—and Dufaycolor—a three-colour mosaic screen process introduced in 1934 in 35 mm., 16 mm. reversal film, and later as a 35 mm. negative-positive process.

Subtractive Processes. The most successful colour cine processes have been those based on the principle of subtractive colour reproduction. Among the earliest examples were Prizma Color, devised by Van Doren Kelley in 1919. From this system, a two-colour method using a double-coated film, chemically toned in two subtractive colours, was derived a host of later processes.

In 1915 the Technicolor Motion Picture Organization was formed, and first produced an additive process. Then a two-colour process was devised using a beam-splitter camera and dyed relief positives, cemented back to back; this system was operated from 1922 to 1928, when the process was then changed to two-colour imbibition printing. In 1933 the first three-colour Technicolor film, Walt Disney's *Flowers and Trees*, was produced, and in 1935 the first Technicolor feature film, *Becky Sharp*, was made. The process has since then maintained immense popularity.

1935 saw the introduction of the first successful three-colour monopack reversal colour process—Kodachrome—in 16 mm. and 8 mm. gauges. Other monopack reversal processes have also appeared since then. As a result of research during and after the war a number of monopack negative-positive colour processes are now in current use.

SPECIAL TECHNIQUES

Although the fundamental pattern of cinematography has developed along straightforward lines, numerous ideas have been evolved to produce special effects or techniques as a departure from normal methods. Some of these ideas are as old as cinematography itself; others have been very short-lived.

The Animated Film. The origins of the animated film can be found in the attempts to make silhouettes and painted figures move in the lever and gear slides of the early magic lantern; also in the series of figures drawn for animation by the Phenakistiscope, Zoetrope and Praxinoscope. Emile Reynaud in the 1880's painted many hundreds of images, beautifully executed, on the strips of film used in his Théâtre Optique. The animated films produced by him before the introduction of cinematography were even accompanied by specially written music and synchronized sound effects.

The first successful cartoon films were made by Emil Cohl, working with the Gaumont Company in 1907; other pioneers at this time were J. Stuart-Blackton and Windsor McCay in the United States. An important step forward was made with J. R. Bray's 1914 American patent for the use of transparent sheets enabling figures to be easily animated on a static background. Earl Hurd, in 1915, also patented the uses of "cells" for animation, describing the methods which have become standard for cartoon making. Bray's elaboration of Hurd's patents led to the formation of the Bray-Hurd Company in 1917. In this same year Max Fleischer, the creator of "Popeye", made his first cartoons for Paramount, and "Felix" the forerunner of many cartoon cats, was conceived by Pat Sullivan. Walt Disney made his

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

first cartoon, *Laugh-O-Grams*, in 1921; the first *Silly Symphony* was made in 1929, followed by his first colour cartoon in 1932.

Other forms of animated films have been the silhouette films of Lotte Reiniger, the puppet films of George Pal, Ptushko and Starevich, and the abstract films of Len Lye and Norman McLaren. McLaren, working with the National Film Board of Canada, made many films by drawing directly on to the 35 mm. film strip with dyes and inks; he also carried out experiments in the hand-drawing of sound tracks, and in three-dimensional abstract cartoons.

The enormous production expenses of cartoon making curtails the serious use of the animated film; production is confined mainly to comedy shorts or sponsored cartoons.

Wide Films and Wide Screens. Among the earliest cine apparatus was the 1896 Chronophographe apparatus of Georges Demeny. The width of film employed in this camera was 60 mm., with an image 35 × 45 mm.—four times that of the 35 mm. film. This wide film, although uneconomical, was capable of giving very large pictures of high quality, and was the first of a series of apparatus intended for wide screen projection. Louis Lumière devised for an exhibition in 1900 a 75 mm. camera and projector showing pictures 65 feet wide to an audience of 25,000. R. Grimoin Samson patented in 1897 his Cineorama apparatus, which by means of 10 projectors would project a panoramic picture covering 360° on the wall of a round building. This apparatus, never used because of insufficient cooling of the small projection room containing ten 40 amp arc lamps, was the forerunner of a number of panoramic projection processes.

The first satisfactory method was devised by Abel Gance in 1927. This system employed three projectors, running from the same motor, which projected on to a screen of triple width either a triptych of three different pictures or one large panoramic scene taken with three cameras suitably arranged. Gance made a film, *Bonaparte*, using this system; it had some success, but it was not followed by further productions.

An attempt was made by Paramount and Fox in 1930 to introduce films 56 mm. and 70 mm. in width; also in the same year projection lenses of variable focal length were proposed to allow certain passages of films to be shown on a wide screen.

Wide screen systems were revived again after the war; Cinerama, a process using triple cameras and projectors to present a combined picture of great width and height was first introduced in 1952. The high cost of installation of projection equipment restricts the process to relatively few theatres; a variety of simpler methods have been introduced to overcome this difficulty.

One method employs anamorphic lenses which record a wider angle of view than normal by laterally compressing the image on the film. A similar lens fitted to the projector expands the image to its original proportions on the screen. With such lenses a picture of aspect ratio (the ratio of height to width) of 1 : 2·66 can be produced, compared with 1 : 1·33 in the conventional film. The anamorphic lens was invented by Henri Chretien in 1927, and publicly demonstrated in 1937. It was first commercially exploited in 1953 as CinemaScope. A simpler system of widescreen projection uses standard films, masked in the projector gate to ratios of up to 1 : 2, projected with short focal length lenses on to wider screens.

These wide-screen processes brought with them two disadvantages: loss of quality due to over-enlargement of the images on the film, and lack of compatability between projection apparatus for different systems. The first process effectively to overcome both disadvantages was Technirama, in which a "double-frame" horizontally arranged 35 mm. negative film can be printed to produce "squeezed" anamorphic prints or normal prints in any film size from 16 mm. to 70 mm. The use of a negative image twice the normal area gives a great improvement in clarity, a principle which has also been exploited in the use of films wider than 35 mm. The first process of this kind—Todd-AO is typical; employing a camera negative 65 mm. wide printed on to a print film 70 mm. wide, carrying six magnetic stereophonic sound tracks, it was introduced in 1955.

In recent years systems have been demonstrated in America and Russia in which a large number of 16 mm. or 35 mm. projectors are used to project a 360° panaromic picture on the walls of a cylindrical or hemispherical room—a return to the principle first demonstrated in 1897 by Grimoin Samson!

Stereoscopic Films. As in the case of colour and sound, the problem of presenting motion pictures in relief has occupied inventors from the earliest days of cinematography.

In principle, most processes of stereo cinematography have made use of a pair of stereoscopic images obtained either by a twins lens camera, two cameras, or a single lens camera with suitable beam-splitting devices. These stereo images must be viewed by methods which allow each eye to see only the appropriate image of each pair.

The earliest projection system, the anaglyph, was proposed by A. d'Almeida in 1858 and first demonstrated for motion pictures by C. Grivolas in 1897. It employed a pair of stereo images of complementary colours obtained by dyeing or projection through filters. The coloured projected images, usually red and blue-green, were viewed by filters of the appropriate colours usually mounted in the form of spectacles. Processes based on this system were in use in 1925 and 1935; they were introduced once more in 1950 but were quickly superseded by methods involving polarized light, as the

anaglyph method is unsuitable for colour films.

Although many attempts had been made to employ polarizing materials in stereo projection, it was not until 1932—when a cheap form of polarizer was introduced—that it became commercially practicable.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The first public exhibition of stereoscopic motion pictures by polarized light methods took place at the New York World's Fair in 1939. The TeleKinema at the Festival of Britain in 1951 demonstrated colour stereoscopic pictures with stereophonic sound; in the following year production began in Hollywood on a number of stereoscopic feature films.

The polarizing system enjoyed a brief period of popularity; the difficulties of synchronization and registration of both images, the necessity to use two projectors simultaneously, as well as the need for the spectator to wear analysing spectacles, led to its abandonment in favour of the wide screen techniques.

It is interesting to note a British patent was issued to G. R. Wilson in February 1898 in which the principles of stereo cinematography by both the anaglyph and polarizing methods were outlined; apparatus was described, similar in principle to that of recent years, involving the use of synchronized cameras and projectors.

Another method, known as the parallax stereogram, has also been used for viewing stereoscopic motion pictures. The system relies on a screen consisting of a large number of vertical elements—wires, slats or embossed lenticles—in the form of a grid, by means of which each eye sees only the image appropriate to it. This method obviates the need for individual analysing viewers. The process, originally suggested by A. Berthier in 1896 and later developed by E. Estanave and F. E. and H. E. Ives, was used as the basis for a workable system by the Russian S. Ivanov in 1941.

Another version of this system was demonstrated by A. Matley of Paris in 1949; called the Cyclostereoscope, stereo pairs are projected on a screen, round which revolves a grid in the form of a truncated cone: as the grid is rotating rapidly, no vertical line structure is visible.

In recent years, methods for the production of stereo pairs on one film instead of the customary two have been devised. Applied to 16 mm. as well as 35 mm. films, these processes usually employ some form of beam-splitting device to produce a pair of stereo images side by side within a standard frame area.

Another development has been the production of stereoscopic projection prints employing Vectograph film. In this, two self-polarized images are actually combined on the one film.

The production of stereoscopic entertainment films has, for the time being, ceased, owing principally to the difficulties of presentation. When these problems have been resolved, we are likely to see further exploitation of the stereoscopic motion picture.

Recent Trends. In recent years, following the development of television, falling cinema audience numbers and increased costs caused a big reduction in the number of cinemas and film production companies especially in the United States. Faced with this competition, the film industry responded with an attempt to recapture lost audiences with spectacular entertainment—colour, "three-dimensional" pictures, stereophonic sound and wide screens of various kinds.

It is likely that further developments in spectacular presentation will be introduced to try and reduce still further the drift from the cinema. With this loss of interest in the cinema, however, has come a rapid increase in the non-professional applications of cinematography.

The use of colour and sound by the amateur has increased considerably. Magnetic and even optical sound projectors are available for 8 mm. film, which, with improvements in film stock and camera design, has recently reached standards of quality formerly associated with larger sizes. This has also been helped by the larger image area of Super-8 film introduced in 1965. For this reason, 8 mm. film is being increasingly employed in science, industry and education, and is likely to find many new applications in the future. B.W.C.

CINE LABORATORIES. Numerous firms specialize in the processing of cine film, operating a similar service to the popular D. & P. service in still photography.

Although some of these laboratories undertake reversal processing, this is normally done by the film manufacturers and is covered in the price paid for the film. Most laboratories deal only in negative processing and positive printing; a few specialize in colour processing and printing.

Laboratories seldom handle all gauges of cine film, most of them accepting only 35 mm. or 16 mm. film. The processing of other gauges is invariably catered for by the manufacturers of the film.

In addition to normal processing and printing, many laboratories can provide optical effects (e.g., dissolves, fades) if required. With some firms, this service extends to providing 35 mm. reduction prints to 16 mm. and other similar facilities.

CINEMA STILLS. Still photographs representing scenes or actors from cine films. These

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

photographs, which are taken for display outside theatres and for press publicity, play a vital part in the economics of film business as a means of creating public interest. A film is an expensive product which has to be sold intensively, and photographs are the basis of the selling campaign.

The still can also assist directly in keeping down production costs, for many firms will lend expensive goods to studios in return for a still which can be used in their own advertising. For example, a manufacturer might lend a luxury model car free in return for a still of a star posing with the car. Stills also have a more permanent value as the guide of the film historian and the inspiration of serious students.

Stills are not enlargements from films. The motion picture camera is constructed to interpret motion on the screen, but its shutter speed is not fast enough to arrest motion. Examination of a long strip of cine film will show that only a few of the pictures have a sharp image. The sharp frames cannot be predetermined, and may turn out to be the least striking single pictures. So, after shooting the scene, the stills are taken separately to provide sharp photographs of well-composed dramatic incidents suitable for reproduction in the press.

Choosing the Shot. The art of the still cameraman lies in selecting the most telling moments in the film story. Because he has to concentrate on this problem, he uses simple standard equipment and employs an automatic technique. The usual camera is an 8 × 10 ins. model with swing back and front movements, which takes a negative the same size as the standard still print. The negative can therefore be easily retouched and used for bulk printing by contact. Quality and speed are all-important in turning out the large quantities of stills required. If the still man used a miniature, he could snap during the cine take and arrest action and save time; but there would be no guarantee that the action would be stopped at the right moment. An instant after the heroine is looking bewitching, she may speak a word which changes her expression disastrously.

The standard technique is modified for violent-action stills—fights, motor smashes, etc.—when dramatic impact is not spoilt if the moment caught is awkward. In this case the still man may shoot with a press-type camera during the actual scene. Outdoor shots, too, are generally action pictures—horsemen riding across moors, yachts racing, etc.—and the still man can make considerable use of his press camera on location.

Stills of an exceptional nature, that are not wanted for bulk printing, are taken with a smaller camera for the advantage of shorter exposures and increased depth of field. An example is the kind of publicity picture taken to show what goes on behind the scenes, which appeals to a limited number of editors.

Lenses. With the standard camera it is customary to use a lens of 12 ins. focal length, as the majority of film stills are medium close-ups. A long shot will not as a rule give the drama, the expression on the actors' faces, or the point of a joke. Long-shot stills are only taken to draw attention to lavish spectacles covering a lot of ground.

Lighting in the studio is controlled by the cine cameraman; but if he is working in low key, the still man, with his slower lens, may require additional light—e.g., he may want an extra flood wheeled to the side of his camera or ask for the diffusers to be removed from lamps. He never likes to increase exposure beyond 1/5 second or the actors might move. But with lighting dictated by someone else, there is not much chance for him to express his individual talent. His opportunity lies in being able to regroup the actors to give the essence of the situation with emphasis but not exaggeration.

Glamour stills of the stars are deemed so important (for the press and for sending to fans) that the still man is given his own studio in which he can pose, light and take close-ups. Here, where mobility no longer matters, he may use a lens of 20 ins. focal length to ensure that the sitter's features are portrayed without distortion. The studio is also used for taking fashion stills of the stars' dresses for press publicity.

Uses for Stills. Apart from his importance in film business, the still cameraman also has some part in film creation. He may take: research stills—e.g., of a costume in a museum for the wardrobe department to copy; location-finding stills to illustrate the photographic possibilities of a district; set stills—i.e., record photographs for use in case sets have to be rebuilt for retakes and continuity stills to record the make-up of an actor so that continuity of appearance can be maintained in scenes shot at a later date.

Other types of picture that the still photographer may be asked to take include the title still, a picture double-exposed behind the credit titles to give them pictorial appeal; the set-dressing still—e.g., a photograph of the star of the film to hang on the wall of a set; an insert still, which may be a photograph of an actor as a wanted criminal printed in a fake newspaper for a story point; or a location background still—a landscape turned into a lantern slide and projected on a translucent matt screen as a background in the Studio.

The increasing popularity of certain three-dimensional films suggest that further developments will occur in the technique of presenting films in depth. At present 3D films are advertised by conventional stills; but tomorrow may bring viewing boxes for stereoscopic samples of exciting scenes installed in the foyers. Yet another category will be added to the list of pictures which the still cameraman has to take.

O.B.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CINEMATOGRAPHY

Cinematography creates the illusion of movement by presenting to the eye a rapid succession of motionless pictures. The illusion depends on a characteristic of the human eye called persistence of vision: when the eye is looking at an object which suddenly disappears, persistence of vision causes the image to linger in the brain for a fraction of a second after the object has gone. To make use of this phenomenon in the showing of a succession of still pictures, each view in the series must appear before the effect of the previous one has died away: the brain is then unable to distinguish the gaps between the separate pictures and an apparently continuous view is seen. If the pictures are progressive and occur at least 16 times per second the series is interpreted as a single picture embodying motion.

But, although persistence of vision causes each image to remain upon the retina for a short time after the stimulus is removed, decay is so rapid that at 16 pictures per second the brain would be conscious of flicker.

To obtain the impression of an evenly lit continuous picture each projected stationary image is further interrupted by means of a shutter so that the retina receives at least 48 separate impressions per second, replacement occurring more rapidly than the period of decay.

Cinematography includes both the making of the pictures and their projection on to a screen. The pictures are taken by a camera equipped to expose a succession of individual pictures or frames on a long strip of flexible film coated with a light-sensitive emulsion. By suitable photographic treatment the film is made to yield a corresponding succession of positive images which, by means of a projector, are thrown in rapid sequence on to a viewing screen.

Mechanics. There are several points of similarity between the camera and the projector. Both are equipped with mechanism that will move the strip of film in jumps of one frame at a time, allowing each frame to remain stationary in the gate behind the lens during the period of exposure or projection and then moving it rapidly into the next position. In both, the lens is covered by a rotating or reciprocating shutter during the fraction of a second that the film is being moved.

The film transport methods have much in common. Above the gate the unused film is stored on a spool or on a rotating centre or core from where it is unrolled smoothly at a steady speed and fed to the gate. There the required intermittent movements are imparted to the film by a mechanical device close to the gate. The basic difference between the intermittent mechanism of camera and projector is that in the camera it must be light and balanced to prevent vibration, while in the projector it needs to be robust to withstand heavy duty use. Below the gate the film is taken away and wound smoothly on to a spool or core on which it is stored.

Except in the simplest equipment the film is fed to and from the gate by sprocket wheels. To prevent damage to the film when it changes from smooth progression over the sprockets to intermittent movement through the gate a loop of film is left above and below the gate.

Films. To enable the rolls of film to be fed efficiently through camera and projector the manufacturers punch specially shaped holes in the film, to come beside or between the pictures, and these perforations engage with the film transport mechanisms. Any errors in the dimensions or positioning of these holes would prevent satisfactory registration and make the projected picture unsteady, so the perforations are made to high standards of accuracy and arranged according to the specifications laid down for the size of film.

Excluding certain non-standard gauges used for special purposes (e.g. 70 mm. film for certain wide-screen techniques) cinematograph films are made in four gauges.

35 mm. (roughly $1\frac{3}{8}$ ins.) is the professional gauge as used in the cinema and is known as the standard size. It is perforated along each edge

CINE CAMERA AND PROJECTOR. Left: *Cine camera with a continuous strip of film being pulled past the lens at an intermittent rate by a suitable mechanism engaging the perforation holes of the film; A shutter covers the lens while the film is actually in motion.* Right: *Projector, using the same intermittent movement principle on the processed film.*

in both silent and sound versions. Film intended for certain wide screen processes differs in some respects. 35 mm. film has 16 standard frames per foot and 4 perforations per frame along each side. The actual frame size depends on whether the film is silent or sound; sound film carries the sound track between the picture and one of the rows of perforations, so the frame size is reduced.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

16 mm. (roughly $\frac{5}{8}$ in.), the widest of the so-called narrow gauge films, has one perforation each side per frame for silent use. The sound version is different because the sound track makes use of the space that would be occupied by one row of perforations. This sound track may be optical or magnetic. Double perforated 16 mm. film with magnetic sound tracks along the outside edge of the perforations also exists. The normal 16 mm. film has 40 frames to the foot and is widely used for documentary film making, educational films and also a certain amount of amateur filming.

9·5 mm. (roughly $\frac{3}{8}$ in.) is perforated in the centre between the frames, so there is only one per frame. Both sound and silent types are the same, the sound track being recorded down one edge of the normal film. At one time 9·5 mm. film used to be a very popular amateur gauge, providing almost as big an image area as 16 mm. in a film only a little more than half as wide. In recent years it has, however, lost a great deal of its following. Like 16 mm., 9·5 mm. film has 40 frames per foot.

8 mm. (roughly $\frac{5}{16}$ in.) is really 16 mm. width film with double the number of perforations. In double-8 mm. cameras, the 16 mm. wide film is run through the camera twice, half the width being exposed on each run; it is then split after processing into two 8 mm. widths, each with a perforation now along one edge only. This film has 80 frames per foot of single 8 mm. width. Super-8 mm. of the same width but supplied in chargers or cassettes of single-8 mm. film has about 72 frames per foot with a larger image size and smaller perforations. This involved less waste and more efficient utilization of the film surface. In either form, 8 mm. represents the most economical film gauge. It is therefore also the main material for amateur cinematography, though its use is also spreading into the professional and educational field. The growing popularity and improved quality of modern 8 mm. sound film has helped this development.

8 mm. film can also carry a sound track in the form of a magnetic stripe along the film edge between the perforations and the edge itself. Alternatively, an optical track can be accommodated there. On Super-8 mm. film, the track is along the unperforated edge.

The majority of 8 mm. films are reversal colour materials (the overwhelming proportion of 8 mm. film used is colour). There are also some black-and-white reversal materials in this gauge. 9·5 mm. films are mainly available as black-and-white or colour reversal materials and 16 mm. films are made both as reversal stock (colour or black-and-white) for amateur use and as negative stock (mainly black-and-white) for professional cinematography. This is because the amateur movie-maker is usually satisfied with a single copy of his film, and reversal processing is the most economical and convenient way of achieving this. Professional motion pictures on the other hand require a number of release prints for projection in various places (running into thousands in the case of 35 mm. film) so there a negative film material is more suitable. The negative-positive process also provides greater scope for a wide variety of special effects obtained during printing the release positive.

For this reason also standard 35 mm. motion picture stock is almost invariably of the negative type (black-and-white or colour) for camera use, and positive film for printing.

Picture Frequencies. Projection speeds have been standardized at 16 frames per second for silent films and 24 frames per second for sound films. It is a fundamental rule that the camera must run at the same speed as the projector if action on the screen is to take place at the same speed as it was performed.

However, camera speeds can be varied, and if the camera runs more slowly than the standard speed the action is recorded on a shorter

CAMERA SPEED. A given movement is recorded on different lengths of film, according to the speed of the film passing through the camera. The film lengths shown correspond to 1 second shooting time: A, fast motion of 8 f.p.s.; B, standard silent speed at 16 f.p.s.; C, standard sound speed at 24 f.p.s.; D, medium slow motion at 32 f.p.s.

length of film than normal—it takes less time to go through the projector and events on the screen happen that much faster.

Running the film more quickly through the camera spreads the action out over a longer strip of film and this will take longer to go through the projector, thus stretching the action and providing slow motion. The slow motion effect is of great value in the analysis of rapid movement, and in some cases a frequency of several thousand pictures a second is used.

At the other end of the scale, the speeding up of slow movements makes possible the production of fascinating films recording such subjects as the growth of plants and crystals. For such subjects the taking rate may be slowed down so that, instead of a few frames per second being exposed, only one per hour or more is taken; for recording astronomical changes, exposures are as few as one frame every twenty-four hours.

It is also possible to make inanimate objects appear to move by exposing individual frames and modifying the subject between exposures—thus a knife and fork can be made to dance a jig. This technique of animation extends to the making of cartoons where the subject is a long series of drawings, each drawing being slightly different from the preceding one.

The Sound Record. When characters on the screen speak it is essential that the picture and sound remain in synchronism. This means that the sound record must be carried on the positive film. But if the sound consists merely of a commentary, such close synchronism is not necessary. This distinction is important when considering methods of recording and reproducing sound.

The sound may be recorded on a track along the edge of the picture film; but far more often it is first recorded on a separate strip of material—either film or tape—which is mechanically synchronized to the picture. The separate sound record may be then later combined on to a final film with the picture.

Two methods of recording the sound are in common use: photographic (or optical) and magnetic. Today the photographic method is becoming increasingly superseded by magnetic recording because of the relative simplicity and cheapness of the latter. The magnetic method is simple because a recording can be played back immediately for checking and can be erased if unsatisfactory; it is cheap because the record can be erased and the material re-used. Photographic sound recording needs expensive equipment and is costly in use.

Cameras. All cine cameras are similar in principle in having a lens, a shutter, a gate and an intermittent film transport. Other optical and mechanical features and refinements vary according to both the film gauge employed and the purpose for which the camera is made.

Most 8 mm. cine cameras, being intended mainly for amateur use, are designed for foolproof and easy operation. Thus the exposure is usually controlled by a built-in exposure meter, modern cine cameras have a variable focus lens and one or possibly two to three running speeds. The intermittent film transport may be driven by a spring or electric motor.

The very simplest 8 mm. cameras are only equipped with a single fixed lens (usually without focusing adjustment), no exposure meter and are virtually the box cameras of movie making. At the other end of the scale, advanced 8 mm. models may have a full range of running speeds, variable shutter, interchangeable or zoom lenses, and a number of further refinements. With very few exceptions these are however still essentially amateur instruments.

The 9·5 mm. camera is also an amateur instrument, and usually on the level of the low to medium price 8 mm. model. A few semi-professional cameras in this gauge also exist.

Cine cameras for 16 mm. film are by contrast usually more versatile, being intended as much for professional as advanced amateur work. The cameras thus may have interchangeable or zoom lenses, reflex finder, variable shutter, and special refinements such as back-winding, large capacity magazines and an extensive range of accessories.

Fully professional versions are generally more robust, and may have electric motors, film capacities up to several hundred feet and provision for simultaneous sound recording.

Film Production. The making of a cine film involves a number of important stages. The actual shooting of a film is only one small part of the many operations needed to produce a complete film.

While an amateur may bring back random shots from a holiday trip and afterwards try to assemble what he has got into a coherent film, anything more ambitious needs a planning routine. This applies to all feature (story) films—amateur and professional—as well as documentary productions.

The first stage is the story outline or treatment, which is the basis for the script. The latter translates descriptions, actions, moods and impressions to be conveyed in the film into a sequence of individual shots. The script specifies as far as possible all the details of the shot, the subject, actors, etc.—and then serves as a fairly rigid shooting guide for the director as well as—later—the film editor.

Once the whole film is planned out in this way, all the sets and scenes selected, properties and other items collected and (especially in professional films) numerous other details organized, shooting itself can begin.

This is then the actual job of filming the individual scenes and actions one by one, setting up camera and lighting as required. In a professional film production the shooting is nearly always carried out by a team. This may consist of as few as two people—director and cameraman—or may include a comprehensive

CC-BY-SA Cunningham Digital Preservation Foundation and Charitable Trust

technical and administrative crew plus the actors and ancillary staff.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

In filming the scenes, visual points and impressions may be put over not only by straightforward recording of what goes on in front of the camera, but also by a variety of camera movements, changes of angle and direction, and a wide range of special tricks.

Processing. Reversal films (black-and-white as well as colour) for amateur use are normally processed by the manufacturer, with the charges included in the price of the film. In the processing laboratory more or less automatic continuous processing machines carry the film through the various stages of development, fixing, colour development, etc. Even professional film makers get specialist laboratories to do the processing work for them, though large film studios usually have their own processing department.

Narrow-gauge amateur films can be processed by the user, though this is a somewhat laborious procedure and requires special tanks and spooling gear to handle the film lengths involved.

A reversal film yields the final image ready for projection on the film that actually went through the camera. Negative films are not projected, but serve as the intermediate stage for making a positive projection print. This invariably requires the services of a motion picture laboratory.

Editing. This is the stage of putting together the final film from the individual shots. They are not necessarily taken in the order in which they are scripted. So the editor not only has to sort out the individual shots, but also cut them to the right length and combine them to convey most effectively the story, moods and filmic effects intended by the director.

For this purpose the editor views all the film lengths on an animated viewer, to judge them technically and artistically and eventually splices them together in their final order for presentation.

In professional productions the sound is also edited at this stage and the sound tracks—usually on separate films—matched with the picture. From the edited version of both image and sound the final release print is produced. The editor also has to order the special effects required for scene transitions, printing tricks (so-called opticals since they are normally obtained by optical printing) and add the titles. These are usually filmed separately.

Projection. To get the best from a film it must be projected to give a sharp, bright and steady picture. In addition the enjoyment of the film can be considerably enhanced by various refinements in the presentation of a show. All these points are as important as the making of the film itself.

Like cameras, so projectors differ in the film gauge they accept and in the purpose for which they are made. For amateur use, 8 mm., 9·5 mm. and 16 mm. projectors are comparatively simple machines, consisting of the light source and optical system to direct an intense beam of light through the film gate, an intermittent movement which transports the film frame by frame from a feed spool through the gate and on to a take-up spool, and a projection lens which projects the image on to the screen. Simple projectors run at a single or two speeds—16 frames per second for silent films and 24 frames per second for sound films. Sound projectors in addition carry the electronic circuits to pick up the signals from the optical or magnetic track on the film and convert them into the sound reproduced through a loudspeaker.

Some 8 and 9·5 mm. projectors have provision for sound reproduction; nearly all 16 mm. projectors are designed for sound films.

Motion picture cinema projectors—for 16 mm. 35 mm. or even wider film gauges—are larger machines with very intense light sources to produce a sufficiently bright image at the high degrees of magnification required for a full scale cinema screen.

The requirements of amateurs are comparatively simpler. They may involve nothing more than setting up the projector and arranging seating accommodation for the audience to view the image comfortably. Projection provisions in lecture halls are more elaborate and those in motion picture theatres are most advanced of all. The latter may incorporate various semi-automatic devices to let a show almost run itself according to a pre-set programme. This covers the change-over from one projector to another while showing successive reels of a film, the control of the sound quality and reproduction, and incidental activities such as the switching of the illumination in the auditorium.

Special projection systems are used for films required for audio-visual presentation—for example in the class room, training schemes, etc. Specially designed projectors are also used for televising motion picture films by projecting the film into a television camera. This requires appropriate synchronization between the projector and the framing rate of the television system.

Scope of Cinematography. The existence of motion picture films is nowadays taken for granted—it is part of everyday life.

Entertainment is, of course, its main business, made up of such varied artistic offerings as the feature films, cartoons, newsreels, documentaries, and fictional films made specially for children. The commercial world also uses films for advertising; and film sequences are made for the television services where direct television is impossible or inconvenient. But 35 mm. film does not have by any means a monopoly of practicability.

Narrow-gauge films had been introduced solely to cater for amateurs and their personal pleasure. But 16 mm. was soon recognized as

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

having great possibilities in serious work. It has obvious advantages in lightness of equipment and lower cost, and so it has been developed to satisfy the modern needs of many different fields.

Good colour is so easily obtained and sound is a routine facility.

Portable equipment and non-flammable film have made 16 mm. ideal for use in schools. Education films cover a range of subjects that is literally world wide. The inclusion of these visual aids at the right places in the curriculum has proved effective in teaching. The appreciation of film is so great in some schools that the children are encouraged to make their own productions which, although fictional, are considered as part of a constructive policy towards the arts.

Most 16 mm. films are nowadays made with sound—optical or magnetic—which is frequently post-synchronized in the form of commentaries, musical background, etc. The use of a magnetic sound track makes it comparatively easy to issue for instance a publicity film in a number of foreign language versions with no more trouble than the transcription of the translated commentary from a master tape to the release prints.

Improved technical quality has brought 8 mm. film into the educational and other semi-professional fields. Even with provision for sound projection, 8 mm. projectors are still more compact than 16 mm. ones and 8 mm. educational films are available, reduction printed from 16 mm. originals.

In industrial circles, not only are there the usual types of informational films for staff training but there are also research needs to be catered for—recording the progress of various processes and experiments, and investigation and fault-finding.

Science directs the eye of the camera into every possible corner. Science newsreels, for example, ably demonstrate the mixture of highly specialized activities such as the use of the electron microscope in the study of micro-organisms, with the more down-to-earth tasks of presenting, perhaps, the growth of plants as influenced by fertilizers. It is a constant urge, this study of subjects that are so often not visible to the common eye—from the amazing depths of the sea to the awe-inspiring depths of space.

One particularly important application of cinematography is in analysing rapid events.

By using high speed cinematography at speeds of well over 1,000,000 frames per second, details too fast for the eye to see can be recorded. This cine technique is widely used in science and industry and has become an important technique of its own.

In the medical world cinematography is employed for the making of training films. It is an ideal medium. Colour is of particular value here and even three-dimensional films have been attempted and found to be effective. Any surgical operations that are rare or have unusual features are photographed as a matter of course and these films are added to the valuable libraries that are being built up. By this means medical knowledge is being spread throughout the world. G.H.S. & L.A.M.

CINEMICROGRAPHY. Cinematography through a microscope, to show the behaviour of living micro-organisms or non-living action phenomena such as crystal growth. Photographically the technique is similar to photomicrography, and the cine camera is mounted above the eyepiece of the microscope, focused on infinity.

A micro-adapter may also be used.

A camera with a through-the-lens viewfinder is useful, but observation of the specimen is usually through a beam-splitting eyepiece of the microscope.

For living micro-organisms the film is usually shot at the normal camera speed; slower or faster speeds may be necessary for other phenomena.

See also: *Photomicrography.*

CINERADIOGRAPHY. Filmed X-ray image, usually of live subjects or of moving machinery. The cine camera photographs the action on a fluorescent screen. As the light intensity of the screen is very low, large lens apertures and highly sensitive films are necessary. Alternatively the radiographic image may be intensified by being projected on the photo-cathode of an image amplifier.

CINE TECHNIQUE

By itself a length of cine film records action and movement. As part of a complete film production it also presents a story and conveys its atmosphere, mood, as well as putting over concepts and ideas in a visual form. These are realized as much by the action recorded as by the combination of different activities, scenes and images.

Making a film thus involves as much planning and preparation as shooting itself. In professional motion picture production, where the running costs of a studio, technicians and artists is very high, the planning is the most important part of production economics—besides being the key to the successful realization of a film story or idea.

The technique of making a film further involves the various aspects of photography (lighting, exposure, camera operation) and a range of effects to present movement and action in realistic or contrived form.

Scripting. Every professional motion picture film starts with an outline, generally referred to as the treatment. This treatment is written in essay or story form. It outlines the idea without worrying about the technicalities of producing it as a film. The technicalities are gone into later.

PLANNING AND PRODUCTION

The treatment, however, already visualizes the film in terms of action and images. In the case of a feature film it may have to convert the literary style and expression of an original story into a pictorial presentation.

Once the treatment has been approved the script is written. This means that the subject matter is painstakingly divided up into scenes, preferably by someone who has sufficient technical knowledge to write only what is filmable: this is especially necessary in the case of documentary and other non-fiction films made on limited budgets. The scenes are numbered consecutively and against each item is placed practical information such as location, camera position and movements, and the actors required (with their dialogue, if any).

The script analyzes every activity or sequence of activities into their component parts or shots. These shots are the actual lengths of film exposed in a continuous run. A shot may last from a few seconds to a few minutes; it is very rarely longer.

The script is also a working plan for the film editor when he puts the final film together from the individual shots. The editor may break down scenes still further by intercutting shots. For this purpose he may want alternative versions of the same scene, for example on sets involving big crowds. Such scenes may be photographed by several cameras from different viewpoints to provide the greatest scope for combination.

When the professional script is complete it will be broken down. That is, various detailed lists will be worked out from it giving such information as the number of artistes required and the scenes in which they will appear, the number of scenes to be shot in each set or location, proposed shooting dates, properties needed. There will be designs and plans for constructing and dressing the various sets. These lists and plans enable all the many specialized departments to get to work on the multifarious aspects of preparation.

The script breakdown also enables the shooting of scenes on the same or similar locations to be combined. The scenes in a film are practically never shot in their scripted order. It is rarely convenient to do so, and once a studio set is built up, it would be uneconomical to use it for one scene near the beginning of the film and leave it set up until needed again for another scene near the end. So all the shots requiring the same set are shot as one group irrespective of their sequence in the film. It is the editor's job to sort them out later.

The planning for an amateur film is usually much less detailed and comprehensive. Scripting is, however, still a valuable aid and discipline for the film maker. It helps him to shoot with a purpose and may mean a considerable saving of film which might otherwise be shot wild and eventually discarded as useless.

Preparing to Film. Much of the technique of motion picture photography is the same for both amateur and professional filming. The camera has to be adjusted for exposure, focus, speed (which does not often change from the normal) and viewfinder parallax (where such a refinement is included). The camera will be set up and the most suitable lens chosen to match the subject: if there is only one lens, as with most amateur cameras, then the subject-to-camera distance has to be altered to give the desired image size. Indoors in restricted spaces a wide-angle lens is a great asset for covering large views.

The camera is mostly used on its tripod; and even when the set-up is static a pan-tilt head will normally be used, making the levelling and centring adjustments much easier than if the tripod legs had to be shifted about instead. The pan-tilt head is essential when the scene calls for a panning movement, and setting up will then involve rehearsing the front and end set-ups of the pan. Some pan-tilt heads have a levelling adjustment so that the plane of panning can be set without moving the tripod legs.

The routine of shooting is simpler with silent films than with sound, and with narrow gauge equipment compared with the much heavier 35 mm. For making sound films the

camera and the associated sound recorder may be driven by mutually synchronized motors, and some time must be allowed for the camera to run up to full speed before each shot (or "take"). For making silent films or where the sound is post-recorded, the take can be made immediately the camera has started.

CC-0. Adamjee Digital Preservation Foundation, Chandigarh

There have to be enough technicians to carry out all the necessary duties involved. In professional circles there are many—a case of at least one man to each job. In newsreel and amateur crews each man generally takes on more than one set of duties. An amateur lone-worker will do everything himself, but this he can often manage because his productions are naturally less ambitious. Cine clubs are usually more concerned with keeping everyone occupied and cheerful, so they make the most of the personnel they have.

The director decides on the set-up and the camera-operator arranges the camera; the lighting cameraman deals with the lighting of the scene.

Shot Types. While the camera is running it may itself either be fixed in one spot (for a static shot) or move around for a travelling shot. In either case it may take in a big view or a small one.

According to the amount of the subject area taken in, shots are classified as long shots, medium shots and close-ups, and are described as such in the script.

A long shot takes in the full setting of a scene and may for instance introduce a sequence involving nearer shots in the same setting.

A medium shot picks out a more or less self-contained section of a setting where an action or part of the action takes place.

A close-up shows detail, for example the head and shoulders of an artiste.

There are also big close-ups—for example when just the face or even only the eyes of an actor appear in the picture—and there are occasionally other intermediates such as medium close-ups, etc.

The terms long shot, medium shot and so on tend to be relative to the sequence or group of shots to which they belong. Thus in a travel sequence a long shot might show a whole valley, while an individual house already becomes a medium shot. On the other hand in an indoor sequence a scene taking in a whole room might still be a long shot and a full-length view of a single person sitting in a chair a medium shot.

Travelling shots may be broadly grouped according to whether the camera changes its direction or its viewpoint. In the first group are the panning movement where the camera swings from side to side, and the rather rarer tilt where the camera swings up or down. Either type of swing must be completely smooth (that is why a tripod with a pan-and-tilt head is almost indispensable). If the scene has no other action in it, a pan or a tilt can be filmed at an increased camera speed (for example 32 or 48 frames per second) and carried out more quickly. On projection at a normal camera speed this makes the pan appear more smooth. At the end of a pan the camera should always hold the scene for a second or two before cutting.

If the camera travels as a whole, the movement must still be smooth. In the studio this is assured by a special rolling camera stand or dolly. A hand-held travelling shot, especially with the cameraman walking, is always too unsteady to be satisfactory—except for special effects. For certain types of travelling shot the camera may be mounted on a car, for example when following another car (or running in front of it). Here the slight unsteadiness is less serious, especially when the shot is intended to give the impression of camera movement.

The tracking shot provides a good transition from a medium shot to a close-up (or vice versa). Here the camera moves directly towards or away from the subject. During such a shot the focus setting needs constant adjustment, a job done in a professional camera team by an assistant known as the focus-puller.

With the growing use of zoom lenses, a zooming shot (from which the zoom lens derives its name) may replace the tracking shot. There the camera remains fixed and only the focal length of the lens is continuously changed to give the impression of going closer to the subject.

There is a difference in the effect between a tracking shot and a zooming shot. As the camera changes its viewpoint in a tracking shot, the perspective of the scene also changes: while the subject becomes larger in the picture frame, it becomes also more prominent against its background. In the zooming shot from a fixed viewpoint the perspective remains constant: though the subject grows larger in the picture frame the background details grow with it. In many cases this difference does not matter. Where, however, the camera is intended to move through a scene of pronounced depth, only a tracking shot should be used.

Lighting. The lighting of the subject has to satisfy two main requirements—technical and artistic. Dealing here with the technical, there must be: enough light to give correct exposure; and the difference in brilliance between the highlights and shadows of the subject must be narrowed down until it lies within the available contrast range of the film. Colour film has a more restricted contrast range and control is correspondingly more difficult. In daylight this control is attained by reflecting daylight or shining artificial light into the shadow areas and shading down the highlights. In artificial light the same effect is obtained by adjusting the number, power and position of the lamp units, or by the use of shutters on the lamps.

Professional studios tend to favour arc lamps, tungsten lamps, and compact source lamps, built into lens- or reflector-spotlights for giving hard controlled beams; also large open-faced units to give masses of soft light.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Narrow-gauge workers more often use Photofloods, giving a very white and actinic light but with a greatly curtailed burning life. These are mostly used singly or sometimes in batches of two, three or four, mounted in bowl-shaped reflectors on suitable stands. This type of lighting cannot be made to cause hard shadows like those cast by spotlights.

Quartz-iodine lamps are also useful for amateur filming, and have the advantage of giving light of a constant colour temperature suitable for type A colour film. These lamps also have a limited life (about 15 hours) but remain constant in intensity throughout their burning time.

Portable lighting units may be attached to the camera for hand-held indoor shots. The units consist of a grip fixed to a horizontal bar carrying usually two lamps. The camera is mounted in the centre. The lamps themselves may again be either photofloods or quartz-iodine lamps. Usually they are run from the normal main supply, but units also exist which run from portable accumulators and are thus independent of any house current.

The intensity of the light on the subject is controlled: by varying the distance of the soft lights from the subject; by concentrating or spreading out the beam from the spotlights; and by using shutters or suitable diffusing materials in front of the lighting units.

The shape of the light areas projected from spotlights is also controlled by various types of shield attached to the fronts of the lamps: snoots are truncated cones or tubes with the open end facing forward; barndoors consist of an arrangement of doors hinged on four sides of a square so that they can be flapped over the spotlamp beam independently.

With these devices, or with cut-out masks fitted on the lamps, brilliant light can be thrown into a shadow area of a subject without overlapping on to the adjacent highlight and making it too bright.

The camera lens is shielded from unwanted light rays by: a deep lens hood; adjusting the barndoors; and the use of niggers, which are flat black boards mounted on portable stands so that they can be set at any desired position and angle between light and camera.

Exposure. Before filming can start, the lens aperture required for obtaining correct exposure must be determined. There are two main methods of using exposure meters—the highlight system and the reflected light or average light system; the former is favoured by many cinematographers.

The highlight meter measures the strength of the illumination instead of the subject brightness. As faces reflect an almost constant proportion of the light falling on them it is possible with the meter to make face-brightness remarkably constant for all scenes. This is what most (but not all) cinematographers want, and is known as key-tone measurement. So the exposure for faces is independent of the background, whether this background be in sunlight or shadow, and the amount of sky included in the picture makes no difference.

The majority of amateur cine cameras have a built-in exposure meter which measures the light reflected from the subject. In many cases the meter automatically sets the lens aperture and may do so continuously even during shooting. Such reflected light readings are reliable in about 90 per cent of all cases. But they need correction for exceptionally contrasty subjects, when shooting into the light or when the scene includes a great deal of sky area.

When filming interiors most professionals use a meter that measures the intensity of the light in foot-candles. It is an incident light reading as with the highlight meter. The cameraman knows that he needs a certain number of foot-candles on the subject for him to use a chosen lens-aperture and he adjusts the various lamps until such an intensity is provided. Shadows and highlights are dealt with separately and the difference between them is kept within the contrast range of the film being used. For exteriors the meters used by professionals are usually similar to those available to amateurs.

Artistic Elements. The technical requirements of film-making are one consideration. There is also the artistic side involving various key men, not all of whom concern us closely in this largely technical survey of film production.

In the professional field the producer is the man at the top—he decides on the type and scope of the film and engages suitable technicians to carry the project through.

The script writer is the man with sufficient imagination and technical knowledge to convert the artistry of the original story into a form that suits the visual medium in use.

The art director is an artist able to design the settings that will create a realistic atmosphere suited to the theme.

In the actual filming, the technician who enhances the work of the set designer is the lighting cameraman. The artistic requirements of lighting can be divided into two phases. First there is the general key of the lighting which is adjusted to accord with the mood the director wishes to convey; this is controlled both by exposure and by the balance of light and shade within the picture area. Secondly there is the use of lighting to give artistic emphasis and hold attention to the main interest of the picture and its action.

The camera operator also will have a feeling for the artistic because he is the man who has to carry out the adjustments in each camera set-up and give the right timing to all the camera movements. Composition is a visually important factor that he will sense instinctively, although he may be influenced by any sketches made by the art director.

But the man who has the last word on these questions and who is the most important of the

technicians is the director. Ideally he is the man who understands the abilities and limitations of all the other technicians and can persuade them to work as a unit in the production of the film. He is a combination of the practical and the artistic. He, if anyone, will have the touch that lifts the film into the top class. This art cannot well be described, but the quality of the end product will be influenced by the director's decision on such matters as camera angles; the way in which successive camera positions build up the effect of a sequence; how the camera should be panned or tilted or tracked during a scene, or moved only slightly for a subtle effect; how the characters will move in order to preserve continuity or heighten the flow of the action; and in the preparation of the necessary scenes for any special effects.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

In an amateur—and often even in a documentary—film unit the team is invariably much smaller and most members of it may do several jobs. Thus the producer and director may be one and the same person and he may also write the script. The cameraman may look after both the lighting and the camera operation. Essentially the functions outlined remain however the same within the scope of the film being made.

Shooting. In an amateur production the shooting stage merely involves filming the shots according to the script and often with appreciable improvisation on the spot. As long as the movie-maker keeps notes of the shots as he takes them, he can—since he also handles the film himself at the editing stage—sort them out afterwards without much difficulty.

Where actors participate in a scene, they are rehearsed beforehand to establish their positions, movements and gestures during a shot. The cameraman in the meantime rehearses the camera movements necessary, if any, to keep the main subject where he wants it in the frame during a shot.

For more ambitious productions, and especially professional films, the preparations for shooting itself are rather more elaborate. More detailed rehearsals may be needed not only of the actors but also of the technicians. When the director is satisfied, he gives a word for the take to begin.

First comes the number board. This, written on with chalk, is photographed on the front of every scene to record the name of the film, the scene number, the take number (as any scene may have to be re-taken) and several other relevant items. The information, recorded thus on the film itself and quoted in all the relative documents, will make the work of people like the film editor very much easier. If sound is being recorded, the number board has a clapper mounted on it—a hinged piece of wood that can be lifted and banged down again. This gives both a visual and an audible signal that can be identified, enabling the sound and picture to be synchronized at the editing stage.

While the number board is being held in front of the camera, the director shouts "Camera" and the camera is switched on. As soon as the board has been carried out of the way the director calls "Action"—the cue for the actors to start their scene. To stop the scene the director will call "Cut".

A continuity assistant records details of everything that might change between one take and the next, such as the position of properties and details of movement. The professional continuity girl takes down shorthand notes of all dialogue spoken in each take and types it out in full on the special forms provided. The camera assistant may make technical notes about such items as lighting, exposures and the amount of film used.

In elaborate scenes the continuity notes are supplemented by still photographs. The still cameraman who does this work is also responsible for all pictures taken for publicity, production stills of the set and the camera crew, and the special publicity stills that are made in his own portrait studio.

After shooting, the exposed motion picture film is sent off to the laboratories with any special instructions that might apply, and after the processing the positive film is put into the hands of the editing department.

SPECIAL TECHNIQUES

The technique of cinematography includes the knowledge of a whole range of special effects produced not only by variations from the normal procedure but by tricks of one kind or another made possible by special apparatus. Many effects are by this time so well established that, by professionals anyway, they are almost taken for granted.

The professional is fortunate in that his special effects can be produced for him in the laboratory by means of the optical printer after his negative has been normally exposed and processed.

Transitions. The transitions are the cinematic devices by means of which one scene changes gradually to another instead of there being a sudden change, as with a cut. The three basic types of transition are the fade, the dissolve and the wipe.

With a fade the scene either gets progressively darker until it becomes black (a fade-out) or appears out of blackness (a fade-in). A density wedge, i.e., a neutral filter in which the density increases smoothly and progressively from one end to the other, is sometimes used to obtain fades in the camera: it is slid across in front of the camera lens. The more advanced cameras have a fade shutter—that is, a variable shutter that can be operated while the camera is running and which gradually reduces the exposure to zero for a fade-out, or opens up to full for a fade-in. A cruder method of fading, often used by amateurs, is to close

CC-0. Agamnigam Digital Plesevation Foundation, Chandigarh

SCENE TRANSITIONS. Left: *Fade out. The image becomes progressively darker until it disappears altogether. The following scene then fades in from complete blackness.* Centre left: *Dissolve. The second scene appears weakly superimposed on the first, replacing it.* Centre right: *Wipe. The second scene displaces the first across the frame.* Right: *Wipe fade. The scene is pushed off the frame by blackness.*

down the lens aperture; but this will only work if there is a large enough range of aperture stops to produce a full black, and in any case there will be a variation in depth of field.

To be fully effective, a fade with the lens aperture needs an iris diaphragm which can close down fully. The difficult part of making a fade in this way is the timing of the closing-down stage so that the darkening of the scene is uniform and gradual. An accessory available for certain cameras closes down the aperture at the uniform rate by a motor.

A number of amateur cine cameras also have a variable shutter and may in certain cases link the control of this with a fading motor.

The dissolve is an effect whereby one scene gradually fades away at the same time as another scene gradually appears and takes its place. To produce a dissolve the first scene is faded out by one of the methods described and the camera stopped. The film is then wound back to the beginning of the fade and the next scene is shot with a fade-in that coincides with the fade-out already there.

A wipe is the type of transition in which a line or shape moves or grows on the screen, gradually wiping away one scene and disclosing the other. In the professional version both scenes are in contact along the line of the wipe and, as it is usually impossible to arrange the necessarily accurate timing with a double exposure in the camera, this transition is a product of the optical printer. The amateur compromises: he wipes away a scene by covering the field of view with a black card cut to the desired shape; there is no winding back and the next scene is uncovered from blackness with a similar shaped card. There is here an affinity with a fade, so the transition is more properly called a wipe-fade.

Various other scene transitions (such as iris fades and wipes where a scene emerges out of a rapidly growing hole in the centre of the previous scene) are almost invariably produced by optical means during printing.

A flash-pan is a sudden transition rather like a cut, but conveys the impression as if the camera had rapidly panned from one scene to the other. It is made by concluding a shot with a quick pan away from the subject. This panning movement must be sufficiently rapid to blur the subject beyond recognition. The second scene may be introduced by a similar flash-pan and the two joined in the middle of the pan. In practice, however, it is sufficient to use only the first panning movement to connect the two scenes. It is much more difficult to bring the camera to rest without any jerk and exactly aligned on the view it is to take in.

Slow Motion and Fast Motion. When the film runs at the same speed through the camera as through the projector (for example 24 frames per second for a sound film) the movement on the screen appears as fast as the original movement in front of the camera.

MAKING FADES. Left: *Use of a fading glass; this is progressively moved across the camera lens to reduce the amount of light reaching the film.* Centre left: *Closing the camera shutter (only suitable for cameras with variable shutters).* Centre right: *Closing down the iris. This does not, however, shut out all the light at the end of the fade, leaving an under-exposed, but still visible, image.* Right: *Use of a pair of polarizing filters in front of the lens, rotating them until they are crossed.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

For special effects the camera however may also be run at a different speed. By increasing the rate at which the film runs through the camera and projecting it at the same standard speed, the action on the screen appears to be slowed up. This so-called slow motion adds interest to sport shots as it shows the exact motions—often undetectable by the naked eye—of an athlete or a dancer. It can be used creatively to give a scene a dreamy or unrealistic effect and it is a valuable aid in industrial cinematography for analyzing rapid motion. There the scope of this technique moves into the field of high-speed cinematography.

Some projectors can also be run at a slower speed than the standard one—for example 5 or 6 frames per second. When projected at this speed, a film shot at the normal rate appears on the screen in slow motion, though with somewhat jerky movement.

As already noted, shooting at a higher camera speed can help in making a panning movement smoother. A further use is in filming models, for example a model ship in a tank in the studio. Normally the rolling and pitching of such a ship on waves made in the tank is much too rapid to be realistic. By filming the model at a higher camera speed, the movement is slowed down to a rate where it corresponds to the motion of a real full-scale ship.

By running the camera slower than the framing rate at which the film will be projected (for example at 8 or 12 frames per second for projection at 16 or 24 f.p.s.) all movement is speeded up. This is largely used for comic effects when the shots include people. However it can also serve to heighten the apparent speed of a train or car, etc.

At a slower camera speed the exposure per frame is also increased. So this is a useful way of shooting in poor light conditions, provided no familiar movements give the show away.

Time Lapse and Stop Motion. The principle of fast motion can be extended to the point where the camera exposes one frame every second, every minute or even every hour. This technique of so-called time lapse photography is useful for depicting processes which are normally far too slow to be observed live: the growth of plants, changes of weather in the sky, etc.

For time lapse films the camera operates at the single frame speed, with an automatic unit which exposes a frame at pre-set intervals. For growth studies the plant is usually set up in front of the camera in normal daylight. Immediately before every exposure the timing mechanism obscures the prevailing daylight, switches on lamps (to ensure uniform exposure for every frame). It then switches off the lamps and readmits the daylight after the exposure.

Stop motion involves stopping the camera during the run of a scene, making a change of some kind in the scene and then continuing filming. The effect is one of a sudden change. One can therefore make something or someone appear or disappear in an instant in accordance with the accepted tradition of magic.

Related to these techniques is the art of animation. Here inanimate objects are moved by the cameraman, a little at a time, between exposures. The objects may be three-dimensional as with puppets, or two-dimensional as with flat diagrams or drawn cartoons.

Cartoons are made by photographing a long series of drawings each of which has been drawn slightly different from the one preceding. The changes represent the progressive movement of the portion of the drawing to be animated, such as a cartoon character. To reduce the amount of labour involved in the drawing, a detailed background is usually drawn on a sheet of paper while the animated objects in the foreground are drawn on sheets of transparent plastic (cells).

Reverse Motion. All film speeds can be used with the film travelling backwards in the camera. Reverse motion is a valuable asset to a film-maker, for not only does it make fascinating tricks possible, with events happening in reverse, but a number of effects can be achieved that would be dangerous or impossible filmed in the normal way.

Narrow-gauge cameras are not usually designed to run backwards, but the cameraman can get the same result by shooting with his camera held upside down and then reversing

REVERSE ACTION. To make a movement go backwards on the screen with a camera that has no reverse running, film the action with the camera held upside down. Then, after the film is processed, cut out the inverted section and splice it back into the film again the right way up. On projection the action appears reversed, for example the diver floats up out of the water back on to the springboard. This technique is suitable for 16 mm. and 9·5 mm. films; with 8 mm. the film has to be reversed sideways where a section is inverted to keep the perforations on the same side. That may lead to some loss of sharpness on projection.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

the film end-for-end after processing. This is not easy to do in the case of 8 mm. as this film is perforated along one side only and so will not turn over satisfactorily.

Superimposition. Two exposures can be made on the same strip of film by winding back to the start before the second exposure. This is the method used in the creation of a ghost. For this effect the actor is first photographed against a black background, and the second exposure is on the chosen empty scene where on the screen the transparent ghost will later appear to be walking.

Double exposure is also used in the familiar titling effect where white lettering is superimposed on a scene photographed in a previous exposure.

Split-screen Filming. There is another way of arranging multiple exposures. Instead of making them come on top of each other it is possible to position them side by side so that the two actions appear as though they were taking place at the same time. Only a section of the frame is exposed on each run through the camera, the rest of the frame being covered by a suitable mask (or matte) until it is needed. The masks are usually held in an effects box fitted to the front of the camera.

This method is particularly valuable in scientific work where one series of events is to be compared with a standard controlled series.

Trick Scenery. The technique of masking can be employed in a number of subtle and often more complex ways. Instead of double exposure combined with the use of black masks, only one "mask" is used and it is not black—it is a painted representation on glass of what will seem like part of the real scene, supported in front of the camera so that it will be photographed at the same time as the real scene, without double exposure.

Scale models of foreground objects are mounted relatively close in front of the lens to convey the impression of real objects at a greater distance. The expense of building the upper storeys of tall buildings is often saved by suspending elaborate scale models in front of the camera in this way.

In the Schüfftan process, a mirror set at 45° is used to reflect the image of a scale model at one side while the main subject is seen through areas scraped from the reflecting surface of the mirror.

Substitute Backgrounds. Not only may one add details to a scene to make it complete but there are devices that enable the action in a studio to be portrayed in any desired surroundings. These systems normally employ two films—one of the background, and one for the complete action.

In principle most of these devices date from the earliest days of cinematography. They involve such things as back projection, in which the action is filmed against a screen on to which a projector throws the required background from behind; travelling mattes, whereby a complicated system of masking is used during the film printing to combine separate films as if they were one; and numerous other effects based on similar methods.

Stereoscopy. Normal cinematography exposes one frame at a time (in rapid succession). Three-dimensional cinematography, which is now available to professional and amateur, exposes two frames at a time, taken from viewpoints about 2½ ins. apart.

Special projection arrangements are necessary to show these two separate records superimposed on the same screen area and yet allow the eyes of the audience to view them individually. The modern method is to project and view the two images through a pair of polarizing filters, the directions of polarization of each picture being at right angles to each other. The effect is one of looking at solid objects through the window of the screen. J.C. & L.A.M.

SPLIT SCREEN FILMING. This requires an effects box. Top: Left-hand mask in guides, covering half of scene, and held with a clip during filming. Bottom: Mask in right-hand side up to same centre mark as before. Left-hand mask removed, and right-hand scene filmed after rewinding film.

CINE TERMS

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Accompaniment. Music and/or effects (often recorded on gramophone discs) which accompany the projection of a silent film and are not rigidly synchronized with the picture.

Action Sketch. Rough drawing indicating a stage or series of stages of an action, used in the production of animated cartoons.

Actuality. Film record of actual events, made without use of actors and without reconstructing or interfering with the action in any way.

Actual Sound. Sound effects the origin of which is visible on the screen or present in the scene (dialogue, traffic noises in a street scene)—as distinct from commentative sound.

Amplifier. Apparatus for increasing the strength of electrical impulses—i.e., to step up the signals from the play-back head of a tape recorder or the exciter lamp in a sound projector to a level where they can be reproduced in a loudspeaker. Similarly, an amplifier can amplify signals from a microphone to operate recording equipment.

The amplifier is an essential part of tape recorders, sound projectors, as well as, of course, of wireless and television receivers and transmitters. The amplifier may employ circuits with valves or with transistors.

Animated Viewer. Apparatus for the convenient inspection of film during editing; it provides a slightly enlarged moving picture and is more simple to operate than a normal projector. The speed of film travel is easily variable.

Animation. Apparent movement of inanimate objects or drawings on the cinema screen. The word is also used for the art of creating such movement.

Animation Board. Adjustable board for holding animation drawings in position while they are being photographed, e.g., in cartooning.

Answer Print. The first projection print of a newly completed film delivered by the processing laboratory. Also known as an approval print. It is submitted by the laboratory for the approval of the producer and director who may call for changes in the grading (lightness or darkness) or colour balance in the scenes as printed by the laboratory.

Auto-Couplings. Method of arranging disc recordings so that the continuation of one side of a record is made on a second disc. An automatic record changer will then play the continuations in correct sequence.

Backward Take. Recording of a scene with the camera running in reverse (or held upside down), commonly used for trick effects and in animation. Normal motion then appears in reverse on the complete film.

Balancing Stripe. Second stripe applied to the opposite margin of a striped film to ensure even spooling. A stripe is a magnetic coating applied to the margin of a film and used to record sound.

Beater (or Dog) Movement. One means of producing intermittent film motion in the camera or projector. An arm at the bottom of the gate digs at the lower film loop and lengthens it, thus pulling the film down through the gate. This arm sometimes has locating pins made in it to register in the film perforations.

Big Close-up. Very close shot, taking in only a small area such as part of the human face to draw attention to minute details.

Bin. Large receptacle into which film is allowed to fall while assembling shots or when running film through a viewer or projector. It takes the place of a take-up spool.

Bin Stick. Wooden strip with pegs or clips on which pieces of film may be hung when editing, laid across the top of a film bin.

Blimp. Case enclosing camera (or projector) to reduce mechanical noise. Mostly used for professional motion picture cameras if sound is to be recorded live during a shot. The blimp then prevents the microphone from picking up the camera noise. Projectors only need a blimp if they are in the same room as recording gear for recording a post-synchronized sound track.

Blind Shots. Shots used at the beginning or end of a sound effect in which the origin of the sound is not seen.

Bloop. Opaque, oblique line painted across a sound-track to obscure a splice or defect.

Blooping Ink. Black, opaque ink which is quick drying. It is used for blacking out areas on film and particularly for painting over splices in an optical sound track to render them inaudible.

Bracket. To move the head from side to side through a field of light. A device by which an actor can discover the position in which he is most strongly lit (felt when the light is hottest on the face.)

Breakdown. Analysis of the film script in terms of scenes with the same locations, sets, properties, etc. In this way it is possible to estimate production costs and determine the most practical order in which the scenes should be filmed.

Bridging Shot. A shot used to cover a break in continuity between successive scenes. A cutaway may be used for this purpose to avoid a jump-cut. Also, a close-up of holiday leaflets may bridge a sequence of holiday preparations with shots of the resort.

Bump In or Out. Instantaneous appearance or disappearance of a person or object during a shot. A common effect in animated cartoons.

Business. Incidental action in a film (e.g., lighting a cigarette or cleaning spectacles) which is not strictly necessary from a story-telling point of view and is often introduced during rehearsals by the director or one of the actors.

Call-Sheet. Written summons to attend a rendezvous for filming issued to actors and technicians.

Camera Operator. Person responsible for the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

operation of the movie camera, as distinct from the lighting side of photography. In professional units and some amateur ones the operator works under the supervision of the lighting cameraman.

Capstan. Drum or roller pulling wire or tape through a magnetic recorder.

Cast. Any excess—generally unwanted—of a particular colour in a colour picture. Collectively also the actors in a film feature.

Cell Flash. Bright patch on film caused by reflection of light from uneven surface of a cell into the lens.

Centrifugal Governor. Device using centrifugal force to keep the motor speed of the projector constant.

Cells. Transparent sheets on which animation drawings are traced for cartooning. Cellulose acetate or colourless plastic is generally used.

Change-over. Switching smoothly from one projector to another at the end of a reel so that there is no interruption in the picture on the screen. Certain frames near the end of every reel carry a spot or other mark near the top right-hand corner—the so-called change-over cue. This warns the projectionist to start the second projector.

Clapper Board. Type of take-board for sound films. A hinged flap is banged down on the clapper board to make a synchronizing mark on the sound-track. It is operated by a junior assistant known as the clapper boy.

Close-up. Shot in which the camera is, or appears to be, very close to the subject. If the subject is a human figure a close-up would include head and shoulders only.

Claw Movement. One means of producing intermittent film motion in the camera or projector. The claw is a metal arm with teeth at one end; the other end is attached to a rotating disc which pulls the claw down while a link attached to the arm pulls the teeth into the film perforations and withdraws them as required.

Commentary. Descriptive spoken words accompanying a film, but not comprising dialogue of the action in the film.

Commentative Sound. Sound which is not directly identified with the action it accompanies in the film, such as music or commentary.

Continuity. Easy transition from one shot to the next and from one sequence to the next without awkward breaks or discrepancies.

Continuity Girl. Member of the production team who notes all the details of each take during shooting (the set, lighting, costumes, position of actors) to ensure that no discrepancies or errors of continuity occur between consecutive shots when the material is assembled.

Continuity Shot. Shot takes after a film is completed, for insertion where required to maintain continuity. It may be a bridging shot taken from the stock library, or a shot inserted in the script afterwards.

Continuity Title. Sub-title designed to tell part of the story, not shown pictorially, other than by direct quotation of speech. For example, "Fifteen years later", or the classic, "Came the dawn".

Copy. Reproduction of a reversal or colour film duplicated from the original.

Counterpoint. Use of sound to present an aspect of the story different from, but complementary to, that shown by the picture.

Credit Titles. Printed list of the cast and technical unit responsible for a film. It appears at the beginning, or less commonly at the end, of a film.

Creep. Difference between the tape speed and capstan speed in a magnetic recorder, due to the effects of tension and elasticity.

Cross-cutting. Alternation from one scene to another in editing so that two or more events are represented as taking place simultaneously.

Crystal Pick-up. Type of pick-up producing electrical impulses from a mineral crystal instead of a magnet and coil. It has an extremely high resistance.

Cut. Instantaneous transition from one shot to another. Also the act of trimming and joining film shots together.

Cut-Away. Shot that temporarily draws the spectator's attention from the main action; e.g., a close-up showing the reaction of a bystander to a street fight.

Cutter. Person engaged in film editing. Usually an assistant who carries out the mechanical part of the operation.

Cutting Copy, Cutting Print. Reversal or colour copy or a positive print used solely for editing purposes. The original or negative is cut to match it when editing is completed and is never projected, but carefully maintained as a source of subsequent prints.

Direct Sound Recording. Recording of dialogue as it is spoken during shooting.

Director. Person who is responsible for the creative side of production; he translates the script into a film and is in charge of the actual shooting.

Disc Recording. Sound recorded as a spiral, wavy groove on a disc; the ordinary gramophone record.

Dissolve. Gradual transition from one shot to another, the second being superimposed on the first at the point of transition.

Documentary. Non-fiction film, often stating a point of view on some current topic.

Dog (or Beater) Movement. One means of producing intermittent film motion.

Dolly. Wheeled platform or vehicle to carry the camera for movement while shooting. A shot taken in this way is also known as a dolly shot.

Dope Sheet. List of shots taken, made out by the cameraman or his assistant.

Double Frame. One animation drawing photographed for two frames instead of one. This either halves the speed of a movement or the number of drawings required for an action of a certain time.

Dubbing. Re-recording of sound, e.g., from

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

disc on to tape or film. Also a term describing the technique of replacing a sound track in one language with one in another language, whilst still retaining perfect lip synchronization.

Dupe Negative. Picture negative prepared from a positive picture original and used for the production of married prints.

Duping Print. Positive print made from a negative specifically for the purpose of making a dupe negative.

Edge Numbering. Numbers printed at every foot along the edge of a negative film to facilitate cutting of the negative to match the edited cutting print.

Editing. Process of assembling the component shots of a film into their final order and then cutting them to their final length.

Effects Box. Bellows or box-like attachment to fit in front of the camera lens. It acts as a lens hood and also holds masks (mattes) at various distances in front of the lens for special effects. Alternatively known as matte box.

Effects Track. Sound-track carrying sound other than music or speech.

Erase Head. Magnet or electro-magnet used to remove the varying magnetization representing sound recorded on magnetic tape, wire or stripe.

Establishing Shot. Shot used to present for the first time a new scene, to establish relationship of details to be shown in subsequent shots. The establishing shot is thus usually a long shot.

Exciter Lamp. Lamp used to scan the sound track in a sound projector; it excites the photo cell.

Exterior. Scene filmed out of doors.

Fade. Gradual darkening of a shot on the screen to complete blackness (fade-out) or the reverse effect (fade-in).

Fading Glass. Strip of glass transparent at one end, gradually increasing in opacity towards the other. Passed across the lens while filming, it produces a fade.

Fading Solution. Dye solution for making fades on positive, reversal or colour film.

Fan. Device driven by motor to cool the lamp-house and film in the projector.

Fast Motion. Special technique which produces abnormally fast motion by filming at a slow speed—e.g., eight frames per second, and projecting at a normal speed—e.g., sixteen frames per second.

Film Bin. Large receptacle into which film is allowed to fall while assembling shots or when running film through a viewer or projector. It takes the place of a take-up spool.

Film Horse. Frame on which separate shots are hung in numerical order during editing.

Flapover. Change in the title seen on the screen, effected by turning a card rapidly so that the reverse side is shown whilst the camera is running.

Flashback. Transition from present to past tense in film narrative, often conveyed in the form of a character's recollections. The whole of that portion of the narrative which is related in the past tense is also known as a flashback.

Flash-pan. Movement of the camera quickly away from the subject at the end of a shot so that a quick pan appears to lead straight into the next shot, no cut being apparent.

Flash Frame. First frame or frames of a shot that are over-exposed due to the time lag in the camera motor reaching the correct speed.

Flicker. Failure of persistent vision; the picture is not evenly bright all the time.

Flutter. Effect produced by very quick variations in the speed of a sound recording medium. Similar to wow, but occurring as much faster irregularities.

Footage. Length of film in feet; usually applied to the amount of film run through the camera for a shot or a sequence of shots.

Frame Glass. Sheet of glass used in the production of animated cartoons to press down upon the cells and keep them flat during filming.

Frame Line. Narrow line or area between two frames on a length of cine film.

Framing. Adjustment of the gate mask on a projector to obscure the film perforations; also the positioning of the film in the gate to avoid the frame line showing.

Full Stripe. Magnetic stripe occupying the full width of the unperforated edge of a single-perforated 16 mm. film (0·1 in. wide).

Gate. Component in camera and projector which holds each frame flat and momentarily still behind the lens.

Gate Float. Unsteadiness in the moving picture due to irregular positioning of the frame in the gate.

Gate Mask. Aperture defining the area of the film depicted on the screen.

Governed Motor. Motor which runs at a speed determined by a mechanical governor.

Grading. Estimating the printing exposure for each individual shot in a master negative of a film to produce a correctly exposed print. In a motion picture laboratory this operation is carried out by a grader. Grading also refers to the colour correction required in colour printing. Modern printing apparatus usually controls the exposure from scene to scene automatically by photo-electric measurement.

Half Track. Magnetic coating, $\frac{1}{20}$ in. wide, applied to a 16 mm. sound film to cover half the optical sound-track. Optical and magnetic sound-tracks can thus be used alternately. The term is also applied to recordings on magnetic tape which occupy only half the width of the tape; in this way the other half of the tape can be used by turning it upside down.

Hold. Photography of one animation drawing on several frames so that it appears still on the screen; also used in scripts to indicate that the camera should continue to film a scene even though the action may have ceased.

Hum. Unwanted low note produced when an

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

A.C. mains supply or other low parasitic frequency enters the amplifier used for recording or reproduction. It can be caused by induction in insufficiently screened leads carrying the signal from the recording or reproduction unit to the amplifier.

Humidifier. Device for introducing moisture into the cooling air in a projector. Also a moistened pad in film cans to prevent the film from becoming too brittle.

Inching. Movement of film or magnetic tape sometimes in jumps, an inch or two at a time. It is usually done by manual operation of the projector or recorder so that a particular part of the film or tape can be quickly found or precisely located.

Induction Motor. Electric motor which runs at a speed largely but not entirely determined by the mains supply frequency.

Input. Electrical impulses or voltage supplied to an apparatus.

Inserts. Shots, sometimes unscripted, such as close-ups of letters, newspaper headlines, clocks, etc., in which no actors appear. By their nature it is unnecessary for them to be taken in conjunction with other shots in the same sequence.

Intercutting. Alternation from one scene to another in editing so that two or more events are represented as taking place simultaneously.

Interior. Shot taken indoors.

Intermittent. Film transport mechanism which advances the film one frame at a time—e.g., at 16 or 24 times a second. There are several types of intermittence—claw, dog (or beater) and Maltese Cross.

Inter-Negative. Negative made for the purpose of making release prints—for example from the master negative via a duping print. Also intermediate colour negative made from a reversal master positive, for example in 16 mm. colour filming for making colour release prints. The inter-negative is also made as one stage in making opticals (mixes, fades, superimpositions, etc.).

Jitter. Uncontrolled movement in an animated cartoon. It is caused by faulty animation, tracing or camerawork.

Jump-Cut. A cut which breaks continuity of time by jumping forward from one part of an action to another obviously separated from the first by an interval of time. Also a cut between two similar views of a scene but at different distances from the camera, so that the picture appears to jump forward on the screen.

Key Line. Line of dialogue which reveals the heart of a story situation.

Keys. Animation drawings of the principal positions in a movement. Keys are made of positions where any part of the figure stops, starts or changes direction.

Keystoning. Distortion of the screen image (widening at top or bottom) when the projector axis is not at right angles to the screen. When the projector is tilted upwards, the screen image appears narrower at the top; when the projector tilts downwards from a high level, the screen image is wider at the top.

Lap-dissolve. Gradual transition from one shot to another, the second being superimposed on the first at the point of transition.

Leader. Strip of film at the beginning of a spool used for loading or threading into the camera or projector.

Level Synchronization. Placing of synchronizing marks so that the record of a sound appears immediately opposite the corresponding picture. (As opposed to printing synchronization.)

Library. Collection of stock shots which may be useful for cutting into future films. A stock shot used in a film for which it is not taken is also known as a library shot.

Light Box. Animation desk with glass drawing surface illuminated from below.

Lighting Cameraman. Person responsible for the photography of a film. In some units an assistant operates the camera.

Light Valve. Device for converting electrical impulses into corresponding fluctuations of a beam of light.

Line Test. Sequence of pencilled animation drawings photographed and projected, usually in negative, to check the quality of the animation, before proceeding with finished work.

Lip-synchronization. Synchronization of sound with film, accurate to a fraction of a second, so that speech can be reproduced in synchronism with an actor's lip movements.

Live Recording. Recording of dialogue and other sound made while a scene is actually being filmed.

Location. Natural setting, usually out of doors and away from the studio, where shots for a film are taken.

Long Shot. Shot in which the camera is, or appears to be, at a considerable distance from the subject. If the subject is a human figure it would occupy less than one-third of the height of the picture.

Loop. Short length of film joined at its ends so that it can be projected continuously or repetitively. Used by actors to rehearse the timing for post-synchronized dialogue. Sound films carrying continuous sounds such as wind, sea, crowd noises, etc. may also be made up into a loop for mixing in with other sound effects at different points of the film.

Magnetic Film. 35 mm. or 16 mm. film stock carrying a magnetic layer over its whole surface in place of a photographic emulsion. A number of magnetic tracks may be recorded on the film side by side in the course of extensive mixing operations.

Magnetic Recording. Sound recorded as variations in magnetization of a wire, or of particles in a coating on film or tape.

Main Title. Opening title bearing the name of the film.

Maltese Cross. One type of mechanism for pro-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

ducing an intermittent film movement. The cross which is mounted on the same shaft as a film sprocket serves to move the sprocket round by the space of one picture at a time.

Married Print. Print of a sound film incorporating both picture and sound track; i.e., a normal print of a sound film for projection.

Master. Film from which release copies are printed and which is not itself used for projection.

Master Recording. Complete sound record, usually made on magnetic tape or film, from which the final optical or magnetic recording is later prepared.

Master Shot. Shot covering the action of a long scene which is afterwards broken up by the insertion of close-ups, etc.

Match. Checking of two shots to make sure that one will lead smoothly into the next.

Matte. Mask placed in front of the lens to blank out part of the scene. Mattes are available in various standard shapes, a common one being that which simulates the effect of looking through a pair of binoculars. For more complex effects the masked area can later be exposed, using a different subject, while the originally exposed area is masked.

Matte Box. Lens attachment in the form of bellows or a box with a frame to take masks (mattes) for split-screen and similar trick effects. Also known as effects box.

Medium Shot. Shot which in effect is about midway between a close-up and a long shot.

Microphone Howl. Noise produced when a microphone is too near the associated loudspeaker, resulting in acoustical feedback.

Mid-shot. Shot which in effect is about midway between a close-up and a long shot.

Mix. Gradual transition from one shot to another, the second being superimposed on the first at the point of transition.

Mixing. Electrical combination of sounds or recordings so that they can be reproduced simultaneously through the one reproducing system.

Modulation. Variation in an electric current induced by suitable equipment—e.g., a microphone.

Monitor Speaker. Loudspeaker (usually small) indicating the volume and balance of sound being recorded or reproduced in another room.

Montage. Process of creative editing. The term is also used to signify a series of dissolved shots, suggesting a passage of time, journey, etc.

Mood Music. Music written in various moods and styles for use in films, radio and television, but not for a specific production. Such prerecorded music may be classified by type and filed in music libraries on disc or tape.

Mute. A picture negative or positive of a sound film without its sound-track. The term implies the separate existence of a sound-track for the film, whereas "silent" refers to a film for which no sound-track has been recorded.

Narration. Commentary spoken by one of the characters in a film, but not synchronized with the picture.

Narrow Gauge. Films and apparatus not of the standard 36 mm. type—e.g., 16 mm., 9·5 mm., 8 mm.

Neutral Density Filter. Neutral grey filter used to reduce the light passing through a lens without affecting its colour. With the relatively long shutter speeds used in cinematography, this is sometimes necessary to avoid over-exposure.

Noise Level. Unavoidable noise produced by projector mechanism or by hum and other sources in the sound equipment. Reproduced sound must have a volume level considerably higher than the noise level for satisfactory quality.

Non-sync. Recording reproduced without provision for precise synchronization with the film.

Notched Titles. Titles printed only on two or three frames and preceded by a notch in the edge of the film. On some obsolete projectors the notch trips a mechanism which arrests the film motion while the title is being read.

Number Board. Also known as take board. Board held briefly in front of the camera and photographed at the beginning of a take. It records the title of the film, the number of the scene and the number of the take, to enable the editor to identify every shot. In sound film production the number board incorporates the clapper and is then known as the clapper board.

Optical Printer. Printing machine for producing positive copies from a negative (or vice versa) by re-photographing the negative image on to the positive film through a lens system (the alternative way of printing is with a contact printer). Optical printers are used for special effects and trick work, and for making reduction prints—e.g. 16 mm. prints from a 35 mm. original.

Opticals. Dissolves, fades, etc., made by the processing laboratories on an optical printing machine after the scenes have been photographed normally.

Optical Centering. Method of centering the film in the gate by moving the optical system instead of the gate mask. In this way the projector need not be constantly re-aligned with the screen.

Optical Effects. Dissolves, fades, etc., made by the processing laboratories on an optical printing machine after the scenes have been photographed normally.

Optical Recording. Recording of sound photographically on a sound track along one margin of a film. This track modulates the light passing through it from a special lamp, and the light impulses are electrically converted into sound.

Output. Electrical impulses or voltage delivered by an apparatus.

Overlap. Double thickness of film at a splice.

Overlay. Transparent sheet on which part of

CC-0. Ayesha Jalal Collection. Digitized by Digital Preservation Foundation, Chandigarh

the design for a title or a cartoon or painted

Pan. Movement of the camera from left to right or from right to left while taking a shot.

Pan Blur. Movement of the camera quickly away from the subject so that a quick pan appears to read straight into the next shot, no cut being apparent.

Parallel Action. Common form of film narrative in which events are represented as taking place simultaneously in different places by cutting from one to another.

Participation Shot. Shot in which the spectator associates the camera eye with the eyes of a character in the story.

Persistence of Vision. Inability of the human eye to separate individual images in rapid succession. This makes the illusion of movement possible in motion pictures.

Pick-up. Instrument using a needle or stylus to follow the waviness in the groove of a gramophone record and so generate corresponding electrical impulses.

Pilot Commentary. Shot by shot description of a film, recorded during screening as a timing guide for subsequent recording of commentary free from projector noise.

Pinch Roller. Roller holding wire or tape in firm contact with the capstan of a magnetic recorder.

Play-Back. Reproduction of a sound track in a studio during shooting to enable additional sound or action—or both—to be synchronized with it.

Post-synchronization. Recording of dialogue and other sound after production so that it matches the already existing lip movements and actions in the film.

Potentiometer. Electrical resistance with provision for drawing of a variable proportion of the voltage applied to its ends. Usually takes the form of a circular casing with a projecting spindle. Rotation of the spindle moves a contact connected to the middle one of three connexions and so selects more or less of the voltage between the other two connexions. It is commonly used for volume and tone controls.

Presence. Illusion of sound which, although coming from the screen, gives the impression of reality.

Pressure Plate/Pad. Device to enable background and cells for an animated cartoon to be photographed flat at even over-all pressure. It consists of a sheet of plate glass in a wood or metal frame hinged to the animation board. Beneath it is a pad of felt or several thicknesses of cloth, blotting paper, or sponge rubber. It is also a camera component holding the film accurately in the focal plane in the camera.

Print. Positive copy of a film, usually intended for projection.

Printing Synchronization. Placing of synchronizing marks so that the sound is in advance of the picture, as required for printing and projection. The interval between the sound and the picture is 20 frames for 35 mm. sound film, 26 frames for 16 mm. optical sound film, 28 frames for 16 mm. magnetic sound films, and 56 frames for 8 mm. magnetic sound films.

Properties. Any portable articles appearing in a film, for example furniture, flowers, fountain pens and fishing rods.

Proscenium. Surround to a stage or screen. It is often illuminated by concealed and coloured lighting.

Quick Motion. Trick of filming with the camera running abnormally slow, so that when the film is projected at normal speed, the action is quicker than it was in reality. The opposite of slow motion.

Racking. Alignment of the film in the camera or projector gate so that the frame line is correctly placed in relation to the sprocket holes or gate aperture. Incorrect racking when projecting causes the frame line to appear on the screen.

Record-Playback Head. Electro magnet which serves either to produce or detect local magnetization of the wire, tape or stripe in a magnetic recorder.

Recording Level Indicator. Instrument showing when the recording impulses approach the intensity that would produce overloading—e.g., in a magnetic recorder.

Reduction Gear. Mechanical means of reducing motor speed.

Reel. Spool of film as used on the projector. A reel is also a measure of length, corresponding to about 16 minutes at silent speed of projection or 11 minutes at sound speed (400 feet of 16 mm. or 9·5 mm., 200 feet of 8 mm.).

Registration. Correct position of animated drawings in relation to one another and to the camera. Also the accurate superimposition of the separate images used in some types of cine film printing—e.g., colour.

Register Pegs. Pegs fitted to a metal bar, designed to keep images on separate supports in correct register. The support has punched holes which correspond to the pegs.

Register Pins. Device in camera gate to ensure that each frame of film is in exactly the same position as the preceding and following frames. This ensures good picture steadiness.

Relational Editing. Editing of shots, which have no literal connexion with one another, in such a way as to suggest an association of ideas, as in a simile or metaphor.

Release Print. Positive print of a film intended for distribution—i.e. projection in cinemas, etc.

Retake. Repetition of a scene or take.

Reverse Action. Recording of a scene with the camera running in reverse (or held upside down) commonly used for trick effects and in animation. When projected, the film then shows events in reverse motion.

Reverse Shot. Shot in which the camera's viewpoint is almost exactly opposite to that of the previous shot. For example; a shot of A looking at B following a shot of B looking at A.

Rewinder. Apparatus for winding film on to its spool ready for projection.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Rostrum. Apparatus used in the production of animated cartoons, giving rigid support to the camera and animation board so that they do not alter position relative to each other in an uncontrolled way.

Rough Cut. Preliminary re-arrangement of shots in editing before their lengths are accurately adjusted.

Running Title. Long title which gradually moves up the screen so that the first lines of the title disappear from the top as others appear at the bottom.

Run Out. In animation, to cause a line or shape to grow from a point.

Rushes. Lengths of processed film which are usually viewed before editing by the director and unit immediately the film is returned from the processing laboratories.

Saturation. Condition of a magnetic recording material in which an increase in recording impulse no longer produces a proportional increase in magnetization.

Scene. Part of the action recorded on film with the camera running, or appearing to run, continuously. The term scene is sometimes used in a more general sense to describe any piece of action which appears to be continuous (i.e., is not divided by a lapse of time).

Scenario. Story of the film in its final form from which the director works during production. It usually contains a detailed description of the action, shot by shot, together with settings and camera positions. Sometimes also known as a shooting script.

Scraper. Portion of a splicer which scrapes off the emulsion leaving the film base ready for the application of the cement.

Script. Story of the film in its final form from which the director works during production. It usually contains a detailed description of the action, shot by shot, together with settings and camera positions.

Script Scene. Part of the action which, according to the script, may be recorded in a single shot although the director may often break it down into several. The word "scene" by itself is sometimes used in a more general sense to describe any piece of action which appears to be continuous (i.e., is not divided by a lapse of time).

Sequence. Phase in the development of the film story, roughly equivalent to the chapter in a novel.

Set. Artificially constructed setting used in a film.

Shooting Script. Story of the film in its final form from which the director works during production. It usually contains a detailed description of the action, shot by shot, together with settings and camera positions.

Shot. Part of the action recorded on film with the camera running, or appearing to run, continuously.

Show Print. Alternative term for release print, i.e. projection print of a finished film for distribution and showing.

Single 8. Film stock 8 mm. in width as distinct from double run 8 mm. film which, before cutting, is 16 mm. wide. Single 8 mm. film is nowadays virtually obsolete as camera stock, since practically all cameras take the film in the double 8 mm. form.

Single Frame Exposure. Exposure of one frame at a time instead of running the camera continuously; a method used in animation.

Single-system Sound Camera. Camera in which picture and sound are recorded simultaneously on a single film.

Slipping Clutch. Device which allows automatic adjustment of the relative revolving speed of spools.

Slow Motion. Trick of filming with the camera running abnormally fast so that when the film is projected at normal speed, the action appears slower than it was in reality.

Special Effect. Illusion either realistic (e.g., a snowstorm) or fantastic (e.g., a character rendered invisible) introduced into a film by means of technical trick work.

Splice. Join between two pieces of film, or the process of joining film.

Splicer. Apparatus for joining film.

Split Track Recording. Method of independently recording several sounds side by side in the width of one normal track on magnetic tape or stripe so that the recordings are reproduced simultaneously.

Spoken Title. Dialogue rendered in the form of a sub-title.

Sprocket. Toothed drum driving the film by engagement with the perforations or sprocket holes.

Sprocket Holes. Holes in cine film by which the film is driven through the camera and projector. They are placed on the edges of 35, 16 and 8 mm. film, and between the frames in the centre of 9·5 mm. film.

Sprocket Modulation. Throbbing of the reproduced sound due to the presence of sprocket holes close to the sound-track.

Sound Drum. Comparatively large roller carrying the film in a projector at the point where the sound-track is scanned.

Sound Head. Components in a sound projector or tape recorder that actually converts the recording into electrical impulses.

Sound-Track. Photographic record of sound on film.

Standard Film. Cine film 35 mm. in width.

Start Marks. Marks on a film and a disc or tape so that the picture can be started in close synchronization with the sound.

Stereophonic Sound. Reproduction of sound so that it seems to have depth and direction, even when the original source is moving—e.g., the sound of an actor's voice actually moving across the screen with the image. In principle it is very similar to stereoscopic photography.

Still. Photograph of a scene from a film or a scene in the making; a normal photograph as distinct from a cinematograph shot.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Stock. Cine film before exposure.

Stock Shot. Shot used in a film, but not taken specially for it; shot taken from a film or library source outside the unit producing the film. Alternative name for library shot.

Stop Action. Exposure of one frame at a time instead of running the camera continuously; a method used in animation.

Story Board. Board to display the action and layout sketches of an animated cartoon in sequence.

Straight Cut. Normal transition by cut as distinct from a dissolve or fade.

Stripe. Magnetic coating applied to one or both margins of a film and used for recording sound.

Stroboscopic Disc. Rotating arrangement of dark and light radial lines which appear stationary when illuminated by light flickering at a related frequency.

Sub-Standard Film. Cine film less than 35 mm. in width—e.g., 16, 9·5 and 8 mm. Nowadays usually known as narrow-gauge.

Sub-Title. Explanatory wording commonly incorporated in a silent film either to replace dialogue or to bridge a gap in the story.

Supersonic Bias. High frequency impulses mixed with the impulses to be recorded. This reduces the distortion of a magnetic recording system.

Synchronization. Accurate co-ordination between sound and its relevant picture.

Synchronizer. Usually two-way or four-way. Apparatus through which two or more lengths of film, either picture or sound track, can be drawn in step with one another for editing or track laying purposes.

Synchronizing Mark. Reference mark enabling separate picture and sound record to be brought into step.

Synchronous Motor. Electric motor which runs at a speed determined solely by the mains supply frequency.

Take. One recording of a shot. One shot is often filmed several times and the best take selected.

Take-board. Board on which scene numbers, take numbers, etc., are recorded and filmed before each take. This information is of great use to the editor when subsequently identifying and assembling the scenes. In a sound film production the take board incorporates the clapper and is then frequently known as the clapper board.

Take-up. Reel or core winding up the film after it leaves the gate of the camera or projector.

Tape. Narrow plastic or paper ribbon coated with magnetic oxide and used for magnetic recordings.

Tempo. Impression of pace in a film created by the relative length of each shot within a sequence and by the speed of the action within a shot.

Throw. Distance from the projector to the screen.

Tilt. Up or down movement of the camera whilst taking a shot.

Title. Lettering of any kind, either explanatory or in the form of dialogue in silent films.

Title Card. Card on which the lettering is arranged or inscribed.

Title Frame. Surround to ensure accurate alignment and centering of a title in filming.

Tracking Shot. Shot from a camera that is travelling forwards, sideways or backwards. Often used to follow moving subjects. A zoom shot, which is much simpler to take since the camera is stationary, is sometimes substituted for a tracking shot.

Trailer. Blank film at the end of a reel after the last shot; also short film of extracts used to advertise a forthcoming attraction.

Travelling Matte. System used to combine selectively images on separate films so that they appear to have been taken on only one film at one time and place—e.g., an actor against a jungle background. It is normally achieved by making a series of silhouette masks from the original films and interposing them during the printing stage.

Treatment. Story of a film in its preliminary form, visualized in pictorial terms but not yet worked out in technical details. The shooting script is compiled from the treatment.

Trip Gear. Apparatus which enables single frames of film or a succession of single frames to be exposed at constant speed.

Turret (Head). Rotating mount fitted to the front of a cine camera, which carries two, three or four lenses and possibly their associated viewfinders. The desired lens can be quickly brought into position by rotating the turret.

Two-core Loading. Method of loading chargers which enables the film to be attached to the core in light.

Twin-track Recorder. Magnetic tape recorder in which less than half the width of the tape is used at once so that interchange of the spools enables a second recording to be made on the same length of tape.

Two-Shot. Medium close-up taken so as to include two people only, head and shoulders.

Two-Way. Brief term for two-way synchronizer. Apparatus consisting of duplicate sprockets mounted on a single spindle for running two lengths of film (picture or sound-track) in step with one another.

Unit. Personnel engaged in making a film.

Variable Area Recording. Optical sound recording in which the track consists of clear and opaque areas, the complementary widths of which vary from point to point along the track.

Variable Density Recording. Optical sound recording in which the light absorption of a constant width track varies from point to point.

Wild Track. Sound-track recorded independently of a picture and intended to be cut into the main track later.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Wipe. Transition from shot to shot in which a line appears to pass across the screen pushing off the first shot and revealing the second shot.
Work Print. Reversal or colour copy or a positive print used solely for editing purposes. The original or negative is cut to match it when editing is completed and is never projected, but carefully maintained as a source of subsequent prints.
Wow. Slow wavering effect produced by uneven movement of the recording medium during sound recording or reproduction. Often caused by uneven transmission in the motor drive.
Zoom. Change in apparent distance between camera and subject, effected by a variable focus lens, during actual filming. T.R. (L.A.M.)

Book: *ABC of Film and TV Terms*, by O. Skilbeck (London).

CIRCLE OF CONFUSION. The average human eye cannot distinguish between a true point and a disc of a diameter smaller than 0·01 in. (0·25 mm.) looked at from a distance of 10 ins. (25 cm.). In other words, any patch of light or shade with a diameter less than 0·01 in. appears as a sharp point. This figure fixes the acceptable standard of sharpness, or "circle of confusion", for a photographic print intended to be viewed from a distance of 10 ins. That is commonly regarded as the normal viewing distance and is a suitable range at which a healthy unaided eye can look at things without fatigue.

If the print is an enlargement, the negative will be generally very much smaller and will have to conform to a stricter standard of sharpness, and therefore a smaller circle of confusion. Again, while a contact print from the negative would generally be viewed at less than 10 ins., a poster-size enlargement would be viewed at a much greater distance. In each case the circle of confusion would have a different value. But at the proportionate viewing distances, the sharpness would appear the same.

There are two ways of approaching this question: the first relates the viewing distance to a standard image perspective, the second to a standard degree of print enlargement.

SHARPNESS AND VIEWING DISTANCE. Top: *A small enlargement must be viewed from nearer than a big scale enlargement (even if from only part of negative) for natural viewing perspective.* Centre: *The limiting blur or circle of confusion is smaller in a print viewed closely.* Bottom: *The more the negative is to be enlarged the finer must be the image resolution, since lack of detail becomes more apparent.*

Viewing Distance. The first approach assumes that to see a contact print image in its correct perspective it must be looked at from a distance equal to the focal length of the camera lens that took the picture. We should therefore hold a contact print 4 ins. away from the eye if the negative was taken with a 4 ins. lens, 8 ins. away if the negative was taken with an 8 ins. lens, or 2 ins. away if we used a 2 ins. lens.

Another way of stating the same thing is to say that a picture taken with a 4 ins. lens must be enlarged 2½ times for correct viewing at 10 ins.

In this way the image subtends the same angle at the eye as the subject did when the photograph was taken. This is said to be the most natural way of viewing a picture.

But if a print has to be viewed from less than 10 ins. the actual diameter of the circle of confusion must be reduced because at closer range the eye can observe smaller degrees of sharpness. If the limited diameter is 0·01 in. 10 ins. away, it will be only 0·004 in. from 4 ins. away and 0·002 in. from 2 ins. away (this case would call for a magnifier to observe the image).

So a lens of 2 ins. focal length must have a circle of confusion five times smaller than a 10 ins. lens, and a 4 ins. lens must have a circle of confusion 2½ times smaller, and so on.

In each case, however, the circle of confusion is 1/1000 of the focal length—i.e., 0·01 in. for a 10 ins. lens, 0·002 in. for a 2 ins. lens and 0·004 in. for a 4 ins. lens.

This is a satisfactory way of arriving at the circle of confusion of "normal" lenses where the focal length is approximately equal to the diagonal of the negative. The rule does not apply to close-ups where the distance between the lens and the plate is very much greater than its focal length.

Scale of Enlargement. The above method of fixing the size of the circle of confusion assumes that every photograph is looked at from the distance that gives the right perspective. But this is not true. An 8 × 10 ins. enlargement from a negative taken with a 2 ins. lens would normally be looked at from the customary viewing distance of 10 ins. The negative, in this case, would probably measure 1 × 1½ ins. and be enlarged at least eight times. But for correct

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

DEPTH OF FOCUS. Circle of confusion determines depth of focus. A cone of rays from the object point O meet at I after refraction by lens EF, and diverge again towards GH. Up to AB and CD (diameter of circle of confusion) the blurring of I is too small to be noticeable the limiting distance D is the depth of focus and represents the tolerance in the lens-image distance for sharp focus. Depth of field follows from analogous, though not identical, geometry.

perspective viewing at 10 ins. a negative made by a 2 ins. lens must be enlarged only five times. An 8 × 10 enlargement should, in theory, be looked at from a distance of 10 × 8/5 = 16 ins. to give the correct perspective effect.

Since people will insist on looking at big enlargements from too close a viewpoint, the "normal" circle of confusion with a diameter of 1/1000 of the focal length is not good enough. So for negatives that have to be greatly enlarged, lens makers tend to adopt circle of confusion diameters of 1/1500 or even 1/2000 of the focal length.

Long and Short Focus Lenses. Nowadays many cameras can be used with a range of lenses, some of longer and some of shorter focal length than the "normal" lens. A 35 mm. camera, for instance, with a "normal" lens of 2 ins. (5 cm.) focal length may use a telephoto lens of 6 ins. (15 cm.) focal length, or greater. According to the rules of correct perspective, the negative taken with such a lens should be enlarged 10/6 = 1·6 times.

In practice, of course, the telephoto lens is used to give a magnified image of a distant object, and the perspective is not considered at all. So the negative taken with a telephoto lens is enlarged by the same amount as a negative taken by a normal lens.

By the same reasoning, the negative taken by a wide angle lens is enlarged on the same scale. In this way each lens shows its characteristic magnified, normal, or reduced scale of reproduction for the same amount of negative enlargement. But only the normal lens will produce normal perspective; both long-focus and wide-angle lens pictures will show distortion at the normal viewing distance of 10 ins.

The final effect on the circle of confusion is simply this: all lenses intended to be used with the same negative size have the same circle of confusion, irrespective of their focal length. And the circle of confusion is in all such cases the same as the circle of confusion demanded for the "normal" lens for that negative size.

So the circle of confusion chosen for any lens depends on the size of the negative it is to cover. If a 6 ins. lens is intended for use as a long focus lens on a miniature camera, it will have a smaller circle of confusion than a 6 ins. lens intended for use as a normal lens on a 4 × 5 ins. camera.

In the same way, the circle of confusion for a wide-angle lens is larger than when used as a normal angle lens on a smaller negative.

This difference affects hyperfocal distance and depth of field values as well as the acceptable amount of blur in calculating shutter speeds to arrest movement, and tolerances in lens correction.

Each case calls for three sets of values for each focal length of lens, depending on whether it serves as a normal, long focus, or wide angle camera lens for that negative size.

For calculations it is still most convenient to relate the circle of confusion directly to the focal length of the lens. We can do that by multiplying the hyperfocal distance—for depth of field calculations—or dividing the subject distance—for shutter speed calculations—by the "power" of the long focus or telephoto lens. This is the ratio:

$$\frac{\text{focal length of long focus lens}}{\text{normal focal length for the negative size}}$$

For long focus and telephoto lenses this factor is always greater than 1.

With wide angle lenses the factor corresponding to the "power" of the lens is given by the ratio of:

$$\frac{\text{angle of view of wide angle lens}}{\text{angle of view of normal lens}}$$

L.A.M.

See also: *Circle of least confusion; Depth of field; Depth of focus.*

CIRCLE OF LEAST CONFUSION. Since no lens is perfect, the image of a point source is not a true point but a small patch of light, circular on the lens axis. As the lens is moved in and out of focus the patch varies in size. When the patch is at its minimum diameter, and the image, by implication, is in correct focus, the patch is then often described as the "circle of least confusion".

The concept of circle of confusion, and therefore circle of least confusion, is essentially theoretical, and is simply intended to be used as a basis for the ready calculation of sharpness requirements. It assumes that the image patch is an evenly illuminated disc, whereas in practical optics this is not so, and the over-all diameter is not, in itself, the sole criterion of definition.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

For example, a patch consisting of a bright central area with surrounding halo (such as frequently occurs behind the image plane, and therefore records objects behind that focused on) gives better definition than a patch of the same over-all diameter, but with a bright peripheral ring (such as frequently occurs in front of the image plane, and therefore records objects in front of that focused on).

Such characteristics vary from lens to lens and determine the actual performance in practice. This covers the quality of a slightly out-of-focus image and therefore the actual depth of field, as well as the position of best focus.

See also: *Circle of confusion.*

CIRCUS. There are two principal reasons for regarding circus photography as a distinct subject and not merely as another type of theatre photography: the lighting comes mostly from directly overhead; the audience encircles the performers. These factors largely govern the choice of equipment and the best technique for taking photographs.

The lighting usually comes from above and tends to be concentrated on the centre of the ring. Spotlights are occasionally used from the side of the ring. There is rarely any change of colour or brilliance in the lighting from start to finish of the performance.

Because the audience encircles the ring, there is a wide choice of viewpoint, but only certain positions are suitable for photography. The performers always play to the higher priced seats so the photographer should take care at least not to sit on the opposite side of the ring or he will get little but back views. A ringside seat will be too close to take in much of the ring but it is useful for close-ups of individual items. Generally a seat next to the gangway and two or three rows back from the ring is the best compromise, and the photographer can stand up if necessary without spoiling the view of the people behind.

Camera. Practically any good camera with a lens of at least *f* 3·5 and an eye-level viewfinder can be used for circus photography. A miniature camera with coupled focusing or a reflex camera with eye-level focusing gets over the difficulty of focusing by scale in the poor lighting of the auditorium. Where the camera must be focused by scale, it is useful to remember that all circus rings are 42 feet in diameter. It is never possible to use such a small stop that the depth of field covers the whole ring.

A lens of normal focal length covers most of the requirements of circus photography as the photographer is always fairly near the subject. Even a normal lens will not cover the whole of the ring from the second or third row, so a long focus lens is only necessary when shots are wanted of just part of the ring. A deep lens hood is advisable, more especially when the camera is pointed up for shots of the trapeze artistes.

Exposure. For most shots the exposure should be made with the fastest shutter speed possible at the full aperture of the lens. Generally this will be about 1/100 second at *f* 3·5. Slower shutter speeds may be used for acts employing the larger animals—e.g., bears, sea-lions, elephants. It is usually safe to double the exposure meter reading with circus lighting.

There is no point in using anything but the fastest panchromatic material.

With fast moving subjects, the fastest shutter speed possible under available lighting may be still too slow to arrest movement. In such cases, the exposure should be made at the "dead point" in the movement (e.g., when a trapeze artiste is at the highest point of his swing).

Colour. The combined use of a fast colour film and a wide-aperture camera lens makes colour photography possible, even when using the available light. Whether photography is possible in any given lighting must be found by use of an exposure meter and through experience. It is essential to expose correctly for the performers in the ring, even if the entire background is thus reproduced black. A correctly exposed background serves no useful purpose, if the main point of interest is and lifeless.

The Subject. There are several kinds of subject: acts on the edge of the ring (clowns) which call for fast shutter speeds; fast moving acts in the ring proper (equestrian items) which also need fast shutter speeds; slow moving animal acts (elephants, etc.) which can be shot at 1/50 second; trapeze turns which may be shot at 1/50 second by careful timing, and the spectators'—particularly children's—faces around the edge of the ring, for which exposures as slow as 1/10 second may often be used. Anything that takes place inside a cage is not worth trying for because the bars are invariably too distracting in the finished photograph.

It is sometimes possible to get a seat at a dress rehearsal. This is a great help in establishing the most suitable viewpoint and technique for the real show. Failing this it is worth while making a preliminary visit with a notebook and no camera.

It is perhaps unnecessary to point out that the photographer should always make sure that photography is permitted (it is often encouraged) and that under no circumstances should any kind of flash photography be attempted. L.V. & F.P.

Book: *My Way with the Miniature*, by L. Vining (London).

CITRIC ACID. Acid used in toners and clearing solutions.

Formula and molecular weight: $(CH_2CO_2H)_2COHCO_2H$; 192.

Characteristics: Colourless crystals with intensive sour taste.

Solubility: Very soluble in water at room temperature, soluble in alcohol.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CIVIALE, AIMÉ, 1823–1893. French army officer and Alpine photographer. Perfected the paper negative process and used it in topography. His equipment for large composite panorama photographs of the Pyrenees weighed 550 lbs. and required 25 men and mules for transport (1887–8).

CLAUDET, ANTOINE FRANÇOIS JEAN, 1797–1867. French daguerreotypist and scientist. Resided from 1827 in London as glass importer. Was one of the first and last to practise the daguerreotype process. Established a supply house for daguerreotype materials in partnership with G. Houghton. Claudet was also an early professional photographer (he established the second photographic studio in London, in 1841) and introduced painted backgrounds. Published in 1841 acceleration process for the daguerreotype. Introduced red light into the darkroom. He was one of the foremost photographic scientists of this early period. He suggested in 1851 the use of series of photographs for the synthesis of motion in the Phenakistiscope.

CLAYDEN EFFECT. Term for the partial reversal of a negative produced by giving the plate or film a very short exposure to an intense light before the normal exposure in the camera.

CLEANING PHOTOGRAPHIC VESSELS. Bottles and dishes that have become stained or dirty in the course of photographic processing can generally be cleaned with a solution of 1 part of strong hydrochloric acid to 3 or 4 of water. This solution removes the lime deposited from hard water. It is this deposit that holds most of the chemical discoloration; when it is removed, the other impurities go with it. The solution must not be allowed to get on to the fingers. and the vessel should be well washed in clean water to remove the acid.

Developer and fixer vessels often acquire a blackish deposit of metallic silver. This can be removed with nitric acid. Developer stains can also be removed by a strong solution of potassium permanganate or bichromate and sulphuric acid (as used in reversal processing); the brown stain is then removed with a 5–10 per cent solution of potassium metabisulphite.

Most deposits on dishes can be removed by the above methods, but stains which have penetrated the surface of porcelain dishes indicate that the glaze is faulty.

There are various ways of removing stubborn deposits from the inside of bottles, but most of them involve the use of abrasives or concentrated acids. Bottles are so cheap that it is rarely worth while using such extreme measures.

If bottles and dishes are well rinsed under the tap and dried each time after use it is a simple matter to keep them clean.

See also: *Stains.*

CLEARING BATH. Any bath included in the processing of a negative or print to remove stains or in some cases neutralize chemicals left by a previous operation.

See also: *Reversal process; Toners.*

CLEAR SPOT FOCUSING. Otherwise known as aerial focusing. A method of focusing in which the ground glass image is dispensed with and the subject focused optically in a clear spot produced by cementing a microscope cover glass to the centre of the focusing screen with Canada balsam or oiling the glass to the ground glass with a drop of cedar wood or similar oil.

See also: *Focusing.*

CLERC, LOUIS PHILIPPE, 1875–1959. French professor of chemistry at the Faculté des Sciences de Paris; also taught at the Collège Technique Estienne physics and chemistry applied to photography, and the theory of photo-engraving, Hon. Professor at the Institut d'Optique. Author of *La Technique Photographique*, *La Technique des Reproductions Photoméchaniques* and other books. Founded *Science et Industries Photographiques* (1921), which under his editorship commanded world wide respect for his exceptionally lucid and correct abstracts.

CLERK MAXWELL, JAMES, 1831–79. Scottish mathematician, physicist and natural philosopher.

CLICHÉ-VERRE. Process in which pictures drawn or painted on glass are copied on to photographic paper. Designs are painted on a glass plate with semi-transparent varnish or oil paint, or scratched with an etching needle on an opaque coating of dark varnish or sensitized collodion darkened by exposure to light. Talbot was the first person to make "etchings" in this manner (*c.* 1835). The technique on varnish was devised, independently of Talbor, by William and John Havell and J. T. Wilmore in London, 1839. Collodion was used as the coating in 1853 by three French amateur photographers, Constant Dutilleux, L. Grandguillaume and Adalbert Cuvelier. Camille Corot, a friend of Dutilleux, made many clichés-verre; so occadid Daubigny, Millet, Théodore Rousseau, and other artists.

The cliché-verre process has been repeatedly re-invented, but has never been able to establish itself.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

CLICK STOPS. Type of iris diaphragm control on camera and enlarger lenses which engages with a definite click at positions corresponding to the standard aperture settings. Lenses fitted with click stops can be stopped down by touch—e.g., in the dark—by counting the number of clicks felt or heard during movement of the setting ring from either end.

CLIFFORD, CHARLES, ?–1863. English Court photographer to Queen Isabella II, in Madrid. Active chiefly as an architectural and landscape photographer and published several volumes of Spanish views in the 1850s.

CLINICAL PHOTOGRAPHY. Medical photography (other than radiography) of parts or the whole of the patient for diagnosis purposes of treatment, progress, etc.

See also: *Dental photography; Endoscopic photography; Medical photagraphy; Ophthalmic photography.*

CLOSE-ACCESS PHOTOGRAPHY. Photographic or cinematographic set-up in which the finished picture is obtained within seconds of the exposure, ready for immediate viewing, evaluation or projection.

See also: *Rapid Access.*

CLOSE-UP CAMERA. Camera unit specially designed for close-up photography, frequently by untrained operators—for example in medical, dental and similar fields.

While many of the more versatile cameras, in particular miniatures, are adaptable to close-up photography with special accessories, a close-up camera usually has such accessories or features incorporated in its design. Thus the lens may be pre-focused to a certain near distance, or set to several shorter distances with the aid of supplementary lenses. The camera often includes a distance gauge or other mechanical probe to set the camera at the right distance from the object. Flash or electronic flash equipment of a specific light output may also be associated with the camera.

The emphasis is on ease of operation and restricted versatility. Hence the simplest close-up cameras are straightforward box models with a built-in flash reflector and a selection of two or three supplementary lenses. A doctor's or dentist's assistant can then take pictures of specific subjects by placing the attached distance gauge or field frame over the object area to be covered and pressing the button. The camera functions automatically look after exposure, sharpness and other technical details. More advanced types may incorporate an optical ranging device—e.g. a beam of light projected through a rangefinder system so that two beams converge into a point at the centre of the object area when the latter is at the right shooting distance.

See also: *Eye camera.*

CLOSE-UP (CINE). Film shot in which the camera appears to be sufficiently near to the subject to show or pick out the kind of detail a person would normally see at arm's length. The close-up of a person would show the head or head and shoulders.

A big close-up goes very near to show up an item of minute detail, e.g. the eyes or the mouth.

See also: *Cine technique.*

CLOSE-UPS

Photographs of subjects which are too close to the camera to be focused by the normal camera focusing mechanism. Close-ups are taken by the use of double or triple extension where the camera is so equipped, an extension tube, or a supplementary lens.

Camera Extension. The extension of the normal camera is governed by the length of the baseboard or the range of movement of the lens mount. With practically all roll film and miniatures this movement permits only a focusing range from infinity to about 3 feet.

Field and other cameras which focus by racking the whole lens board forward or backward usually have a range of focusing movement as much as two, or even three times the focal length of the camera lens. This double or triple extension is used for really close-up focusing in copying and macrophotography.

The object distance for copying to a given scale is given by the equation:—

$$u = \frac{F(M + 1)}{M}$$

where u = Distance of object from lens
F = Focal length of lens
M = Scale of reproduction

The scale of reproduction is always the ratio of image size/object size.

If the image is smaller than the object, the scale of reproduction will be a reduction. For instance, if the object is four times as large as the image, the scale of reproduction is 0·25, or 1/4, or 1 : 4. If the image is larger than the object, the scale of reproduction is greater than 1, and represents a magnification. For instance, if the image is twice as large as the object, this is expressed as magnification 2 : 1, or 2/1, or 2.

Example: the object distance for copying on a scale of 0·5 (a reduction of 1 : 2) with a 6 ins. lens is:—

$$\frac{6(0{\cdot}5 + 1)}{0{\cdot}5} = 18 \text{ ins.}$$

The extension of the lens beyond the infinity setting is given by the equation:—

$$d = FM$$

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

CLOSE-UP FOCUSING. Top: *The smallest image of an object is formed with the camera focused on infinity.* Upper centre: *Moving the camera lens forward focuses it at a nearer distance, giving a larger image.* Lower centre: *The image is larger still (and the subject distance shorter) with the camera focused on infinity, but a supplementary lens placed in front of it.* Bottom: *The largest image and closest subject distance is obtained by moving the lens forward to its nearest focusing limit and adding a supplementary lens.*

Where d = Focusing extension in front of infinity setting
F = Focal length of camera lens
M = Scale of reproduction

The total bellows extension needed is the focal length plus the extension beyond the infinity setting, i.e., d + F or F(M + 1).

For example, when copying on a scale of 0·5 with a 6 ins. lens the focusing extension beyond the infinity setting is:—

$$6 \times 0{\cdot}5 = 3 \text{ ins.}$$

giving a total bellows extension of 9 ins.

At such close quarters the object distance is measured from the front node of the lens. For a single lens this is approximately one-third to one-half the actual thickness of the lens behind the front surface. In practice it is not possible to guarantee sharp focus from calculation and measurement. The final adjustment is done by inspecting the image on the focusing screen of the camera.

The scale of reproduction at any object distance can be found from the equation:—

$$M = \frac{F}{u - F}$$

where M = Scale of reproduction
F = Focal length of lens
u = Object distance from lens

So for an object 24 ins. away from a 6 ins. lens the scale of reproduction is:—

$$\frac{6}{24 - 6} = 0{\cdot}33 \text{ or } 1 : 3$$

i.e., the image is one-third the size of the object.

The scale of reproduction obtainable with the camera fully extended is:—

$$M = \frac{e - F}{F}$$

where M = Maximum scale of reproduction
e = Total camera extension
F = Focal length of camera lens

For a double extension camera where e = 2F the maximum scale of reproduction is 1 : 1, or same size. For a triple extension camera where e = 3F, the maximum scale of reproduction is 2 : 1 or 2 times enlargement.

The image distance (total camera extension) at any reduction is the same as the object distance at the corresponding magnification, and vice versa. Thus the image distance which gives a scale of reproduction of 0·33 (1 : 3) is the same as the object distance which gives a scale of reproduction of 3 (3 : 1) with the same lens.

A double extension covers practically the whole range of normal close-up requirements while a triple extension brings the equipment into the realm of macrophotography. But while it is feasible, although expensive, to fit a double or triple extension to the bellows type of folding camera, it is not a practical proposition with those which have focusing mounts, front cell focusing and other systems. So with such cameras—and those which in any case are only equipped for down-to-3-feet focusing—one of the methods described below must be adopted.

Extension Tubes. These are simply distance pieces which are inserted between the lens and its mount to provide extra camera extension. Such devices can be used only where the camera lens is easily removed—e.g., by a quick screw thread or a bayonet mount. Since the diameter of the tube—especially for long separations—may approach the diagonal of the negative, the method is really only suitable for miniature cameras. With 35 mm. cameras in particular, extension tubes are an excellent means of close-up focusing.

Most of the classic miniatures list ranges of sizes of tubes made specially to suit the various lenses. The set of tubes, used in conjunction with the normal focusing movement of the lens, enables the subject to be brought progressively nearer up to as little as 2 ins. (5 cm.) giving a maximum reproduction scale of 1 : 1.

With cameras having interchangeable lenses and a focal plane shutter, the length of extension tube that can be used is limited only by considerations of vignetting due to the size of the lens mount, camera steadiness and focusing adjustment. The practical limit of such systems is normally reckoned to be reached with magnifications of around 10 ×. But this is merely because at higher magnifications photographing through a microscope becomes more

CC-0. Agamirian Digital Preservation Foundation, Chandigarh

convenient. Here the short focal length of the microscope objective still permits the use of reasonable dimensions in the camera set-up. With a standard 50 mm. lens on a miniature camera a magnification of say 25× would require a lens-to-film distance of some 4¼ feet!

With interchangeable camera lenses mounted in front of a diaphragm shutter, extension tubes can still be used but are much more limited. Since the shutter aperture is in effect some way along the light path between the lens and the film plane, extension tubes of any length would result in appreciable vignetting. Close-ups with such cameras are therefore frequently taken by using a combination of extension tubes and supplementary lenses.

Adjustable extension bellows can also take the place of extension tubes. Such units consist of a front and a rear panel mounted movably on a single or double rail. The distance between the two panels is continuously variable from a few millimeters to several inches. The rear panel fits to the camera body, and the front panel takes the lens or one of several lenses (often with appropriate adaptor rings or fittings). Usually such units are tailored to a particular camera model. Their main advantage is that they provide a continuous focusing movement ranging—according to the lens used—from subjects at infinity down to same size or larger reproduction. The bellows movement may include a calibrated scale marked either in scales of reproduction for a particular focal length or merely with a numerical scale to permit easy reference to a particular noted setting.

With extension tubes, bellows or mounts some means of accurate focusing, preferably with a visual image, is required. For this purpose reflex housings or focusing stages are provided for certain camera models and show the image on a ground glass screen. This is then replaced for the exposure by the camera but with the film plane in the same position as the screen.

For macrophotography the method is practicable up to magnifications of 10×.

Close-up Focusing Mounts. Long focusing extensions are normally associated with the bellows-type technical camera, but helical focusing mounts which move the whole lens forward or back can also be designed for an appreciable focusing travel to include a close-up range. There are two approaches to this.

The first, and older one, has been used with rangefinder miniature cameras with interchangeable lenses. Here the lens is removed from the camera and inserted into a supplementary focusing mount which at the same time also acts as an extension tube. Usually the focusing movement covers subject distances from the near limit of the normal focusing system (around 3½ feet) to about half this distance—i.e. a scale of reproduction of 1 : 6 to 1 : 8 with the standard camera lens.

When used with rangefinder cameras such devices frequently incorporate an optical compensator (for example a wedge) that fits in front of one of the rangefinder windows to provide additional convergence of the rangefinder beams. The rangefinder then indicates the exact focus with the close-up focusing mount as well, and can be used for hand-held close-up photography even of live subjects.

The other and more recent system is the incorporation of a helical focusing mount with extra extension into the lens itself. This may be achieved by double helical movements which in extreme cases cover a range of focusing distances down to same size reproduction. The built-in close-up mount has the advantage that it covers the full focusing range from infinity downwards. Lenses of this kind are usually intended for reflex cameras, since a corresponding rangefinder compensation is difficult to design.

Supplementary Lenses. Where the camera has only the normal focusing range, and the lens cannot be removed, or the camera is otherwise not adapted for extension tubes, close-up focusing can be carried out by adding a positive

EQUIPMENT FOR CLOSE-UPS. Top: In the usual photographic apparatus, the lens is racked out to focus near objects sharply. Centre and bottom: For greater-versatility, a camera with interchangeable lenses permits the use of extension tubes or bellows, and also of a focusing device to ensure maximum image sharpness. A, focusing stage with ground glass screen and focusing magnifier. B, extension tubes. C, camera lens. D, extension bellows. E, reflex housing with ground glass or clear glass focusing screen.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

supplementary lens in front of the camera lens. This calls for no extra extension, although the effect is greatest when the camera lens is at the forward limit of its movement.

When the camera lens is set to infinity, and a positive supplementary lens is fitted in front of it, the combination is focused on objects at a distance equal to the focal length of the supplementary lens, e.g., if a 24 ins. supplementary is added, whatever the focal length of the camera lens, the combined lenses will be sharply focused on objects 2 feet away.

The supplementary lens does not alter the marked values of the camera lens aperture, but if it is a simple, uncorrected supplementary, it degrades the performance of the camera lens. For this reason the camera lens has to be stopped well down if critical definition is required.

Certain high quality supplementary lenses of special correction also exist; these are usually intended for use with a particular camera lens. Interchangeable-lens cameras using a convertible lens system, i.e. where the front lens component is interchangeable for different focal lengths—may include in their range of alternative lens units special macro-lenses. These are suitable front components that yield high image quality at or around same size reproduction.

Focusing Aids and Gauges. Where supplementary lenses are used on a reflex camera no additional focusing aid is necessary. The reflex screen directly shows the image sharpness as well as the field of view taken in.

Various ways exist for other cameras. The simplest is a focusing table showing the exact distance (measured from the subject to either the front of the supplementary lens or to the film plane) for each setting of the camera lens with any given supplementary lens. Such a table requires accurate measurement, which is a little cumbersome in practice.

Handier are close-up rangefinders which fit into the accessory shoe of the camera. These are usually designed specifically for a given camera and set of supplementary lenses. Using them involves setting the rangefinder to the required camera lens setting and power of supplementary lens, and then approaching the subject until the double rangefinder images fuse into one. At that distance the subject will also be sharp on the film.

Distance gauges are available for a number of cameras and exist in versions for either supplementary lenses or extension tubes. They consist of a frame at the end of a rod of fixed length which is attached to the camera. Anything in the plane of the frame will be sharp on the film, while the limits of the frame also outline the subject area taken in. Alternatively, a set of four legs may be fixed to a collar mounted either between the lens and the camera or to the front of the lens mount. In this case the tips of the legs define the plane of maximum subject sharpness as well as the field of view. Frequently such distance gauges serve a set of supplementary lenses, in which case the legs or rod are extendable to several set positions. This type of distance gauge is particularly suitable for close-up copying, since the camera can simply be placed on top of the surface of the original.

Various modifications of the system exist, and work on more or less the same principle.

Field Covered by Lens. The size of field covered at any distance is given by:

$$W = \frac{N}{M}$$

where W = Width of field
N = Width of negative
M = Scale of Reproduction

For instance, photographing on a scale of 0·2 (i.e., a reduction of 1 : 5), the width of the field taken on the long side of a 4 × 5 ins. negative is 5/0·2 = 25 ins. and on the short (4 ins.) side, is 4/0·2 = 20 ins.

Since at close range the lens is considerably farther from the film than in normal photography, a given lens can cover a larger negative format in close-up photography. For instance a 25 mm. lens with a covering angle of 60° would, when focused on infinity, cover an image circle of 29 mm. in diameter. It would therefore be unable to cover the full image area of a 24 × 36 mm. negative. When used at same-size reproduction however the same covering angle corresponds to an image circle of some 58 mm. —which can comfortably accommodate a 24 × 36 mm. negative area. Hence lenses of specially short focal length are frequently used for macro-photography at large magnifications, and lead to more manageable camera set-ups.

Distortion. As the camera gets closer to the subject, the perspective of the picture it sees becomes more and more unpleasant when the print is viewed from a normal distance. There is no remedy for this; the viewpoint and the perspective have a fixed relationship.

The more the subject approaches a single plane, the less the apparent distortion becomes —e.g., there is none in a close-up of a two-dimensional drawing, very little in a sculptured relief, but a great deal in a close-up portrait where the sitter's limbs extend towards the camera. There will therefore be less in a profile portrait than in a full-face, particularly if the sitter has a long nose or jutting chin. There will also be less in a photograph of a dog lying across the picture than if its head is much closer to the camera than its tail. And a child will have more normal proportions if photographed from its own eye level than if the camera looks down on it so that its head is so much nearer—and larger in proportion—than its feet. These examples illustrate the general approach to close-up subjects to preserve natural perspective.

Depth of Field. As the camera gets closer to the

CC-0. Vasishth Digital Preservation Foundation, Chandigarh

subject, the zone of sharpness shrinks closer and closer to the actual focal distance. The effect can be compensated for—up to a point—by stopping down the lens, but at close distance a very narrow zone of sharp focus must be accepted as inevitable. As the depth of field thus decreases, depth of focus increases.

Exposure. Where the camera extension is increased (by bellows or extension tubes) the marked lens aperture has to be increased in proportion to the increased lens-film distance, requiring extra exposure. In addition, a further exposure increase is necessary with near shots because the shadow areas become more important when they are seen close at hand.

When comparatively long camera extensions are used for taking close-ups, the relative lens aperture (*f*-number) must be multiplied by a correction factor to give the correct value for calculating exposures. This correction factor depends on the scale of reproduction:—

True *f*-number = nominal *f*-number × (M + 1) where M is the scale of reproduction.

When the scale is smaller than 0·1 (reduction more than 1 : 10) the error in the *f*-number is less than 10 per cent (one-fifth of a stop) and can be ignored.

Some lenses with built-in close-up mount may have the aperture control ring coupled with the focusing movement in the near focusing range. Focusing the lens on a near distance then automatically opens up the diaphragm to compensate for the required exposure increase.

The Subject. Subjects for close-up photography must be as nearly as possible in one plane if they are to be sharp because the depth of field at short distances is very small. On the other hand, the depth of focus increases and the image on the focusing screen changes only very slowly from sharp to unsharp during focusing.

CLOTH PRINTING. Several processes have been developed for making photographic prints on woven material.

See also: *Fabric printing.*

CLOUD NEGATIVES. Cloudless views can often be improved by printing in clouds from a second cloud negative. Where the skyline is fairly straight, the procedure is quite simple. A selection of cloud negatives is useful.

Simple Shading. First the landscape negative is enlarged in the usual way, but the sky portion is shaded during exposure with a card cut to the shape of the skyline. (It is generally wise to stick scraps of white paper on the margins of the holder to indicate the position or level of the skyline.) The card is kept moving slightly during the exposure to avoid a sharp edge.

Next the cloud negative is inserted in the negative carrier and, with the orange filter over the lens, it is focused and brought into position over the same sheet of printing paper. (A rough sketch of the final effect aimed at is useful as a guide at this stage.)

Finally, the sky area of the print is exposed while the previously exposed foreground area is shaded up to the level indicated by the guide marks on the paper holder.

The cloud and landscape negatives should be alike in the direction of the lighting, viewpoint, and in the character of the daylight—i.e., season, time of day, weather, etc. The exposure times for each negative are best found by separate test strips.

Masking. Where more complicated outlines are to be shaded, fairly accurate masks and counter masks are required. They are used on a masking stage consisting of a sheet of glass supported a little way above the paper holder. It is necessary to allow some space between the mask and the paper so that the image of the mask will be slightly blurred.

The first negative is focused on the paper holder or baseboard, and a sheet of white but fairly opaque paper is placed on top of the glass above it. The outline of the image to be printed is then traced on the paper. The paper is then cut along the line.

The two parts of the paper make up the mask and counter mask. They are fitted together on the masking stage and the outside edge of each mask is taped or stuck down, so that each part can be either folded back out of the way, or brought into position without having to be re-aligned.

With the first negative correctly focused in the enlarger, the lower mask is folded out of the way, and the sky mask is folded down and held in position on the glass plate. The printing paper is inserted underneath the masking stage, and exposed.

After the first exposure, the paper is left in position and both masks are folded down on the masking stage. The orange filter is slipped over the enlarger lens and the second negative is inserted in the enlarger, and positioned so as to fit the outline of the counter mask. Finally the counter mask is folded out of the way, and the second exposure is made.

Exposure times are found beforehand by test strips.

Both negatives must be enlarged to the same degree. If there is any difference in scale, the shadow outlines of the two sides of the masks will not coincide on the printing paper. This discrepancy would produce either a white or a

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

CLOUDS BY COMBINATION PRINTING. 1. Mark out skyline of landscape on a sheet of paper supported on glass platform just above the enlarger easel. 2. Cut out mask and countermask. 3. Fit mask and countermask together on platform, tape down outside edge. 4. Fold mask out of way and expose paper on easel to landscape negative. 5. Bring back mask, remove countermask, and expose to sky negative.

dark line along the boundary of the two images.

For more involved masking it becomes necessary to construct special masking boxes. These are made to hold the masks on one or two glass frames and to allow the printing paper or paper holder to be removed and then replaced in exactly the same position relative to the masks.

CLOUDS. The sky and clouds are often an important part of the scene that the photographer wants to record, but unless he knows how to deal with them, they often reproduce as blank white paper in the resulting print. There are two reasons for this:

(1) All black-and-white negative emulsions are more sensitive to light and medium blue than to any other colour, and

(2) The sky is more often than not the brightest part of any outdoor scene.

Cloud and Light. The greater the contrast between sky and cloud, the easier it is to photograph them, and the contrast varies according to the light and the type of cloud. Some clouds are much brighter than others; the brightest are the "cotton wool" cumulus clouds, and because they generally occur in a dark blue sky, they are the easiest type of cloud to photograph. Cumulus clouds are about twice as bright as the upper part of the low-level nimbus (rain) clouds which tend more to a grey tone. Half-way between those two types in brilliance, are the high, wispy cirrus clouds (mares' tails), but they usually have a very pale sky as background and therefore show very little contrast to the sky.

The darkest part of the sky is always near the zenith but slightly to the north; the blue lightens towards both the sun and the horizon. Just above the horizon the sky is almost white and clouds do not stand out from it.

The direction of the lighting also influences the brightness of clouds. Front lighting produces the greatest reflection towards the camera and therefore the greatest brightness. But what is gained in brightness is apt to be lost in modelling. The sun shining on clouds at an angle of about 45°—i.e., over the photographer's shoulder—produces both good modelling and bright clouds.

Haze. In the course of the day, over-all contrast again varies considerably. The best time for photographing clouds and skies is between one and four hours after sunrise and from four o'clock in the afternoon up to about one hour before sunset. Atmospheric haze always tends to lower the contrast of the scene, and during the middle hours of the day there is much more haze in the atmosphere than at the beginning and end of the day. And there is also more haze in summer than in spring and autumn. The finest and clearest cloud formations are often found in April and May.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

CLOUD TYPES. Left: *Cloud formations and height of occurrence.* A, *cirrus clouds.* B, *cumulus, going over into cumulo-nimbus on lower levels.* C, *nimbus.* D, *rain-carrying storm clouds.* Right: *Filters required to penetrate haze at different heights.* E, *Ultra-violet (higher mountain regions).* F *and* G, *light to medium yellow (low mountain regions).* H, *deep yellow to red (valleys and flat country).*

There is far more haze in the air over the British Isles than in continental climates, and more over big cities than over country districts. The amount of haze diminishes with increasing altitude and disappears altogether at about 6,000 feet in summer and 3,000 feet in winter.

Film. The brighter types of cloud can be photographed satisfactorily against the darker parts of the sky on panchromatic film without the need for correction filters.

Colour. The cloudscape for its own sake is not nearly as often attempted in colour as in black and white, except for sunset effects where colour really does score. The more delicate sunset is better than the lurid type which may come out rather exaggerated. In landscapes where the sky plays a secondary role it usually records well even without special care, and distant clouds are still separated from the sky by the film.

Filters. With black and white film medium yellow or green filters in normal conditions give a true rendering of sky tones; orange and red make them dramatically dark. At high altitudes a U.V. filter provides all the correction necessary; even a pale yellow gives too much contrast.

There are also graduated sky filters in which the tint deepens towards the upper half, and the lower half is quite clear. Such filters prevent over-exposure of the sky while leaving the landscape unaffected: they call for no increase in exposure.

FILTERS FOR CLOUDS

Conditions	*Desired Rendering*		
	Natural	*Crisp*	*Dramatic*
Hazy sky	Medium yellow or green	Dark yellow, green or orange	Red
Clear but little contrast (pale sky)	Pale yellow or green	Dark yellow, green or orange	Red
Blue sky with good contrast	Pale yellow	Medium yellow or green	Orange
Very dark sky with brilliant contrast ...	None	Pale yellow	Medium yellow or green
The same above 6,000 feet[1]	None	U.V.	Light yellow
Sunset with blue sky ...	Pale yellow	Medium yellow	Orange or red
Sunset with red sky ...	None[2]	Pale green or blue-green	
Black storm clouds ...	None	None	None

[1]Distant cloud photography not recommended during the middle of the day.
[2]Light green filter with pan red film.
This table is intended for panchromatic film material. With ortho film double the strength of filters, but use yellow ones only.

With colour film, the only filters that can be used are colourless U.V. filters and neutral grey polarizing screens. These darken the blue of the sky by cutting out the polarized light rays which are reflected principally from just above the horizon. In this case the effect must be studied either on a focusing screen, or by looking through the filter and rotating it until it is in the position that gives the desired effect.

Although all makes of films and filters show as many subtle differences as there are variations in the colour of the sky, the table above will help to produce good results in most conditions.

SUN AND CLOUDS. Side light gives best modelling, back lighting shows greatest contrast, front lighting yields flat results.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

CLOUD ILLUMINATION. Left: *Early morning clouds are delicate against a light sky.* Centre: *Midday clouds show more modelling against a darker sky.* Right: *Evening sky after sunset is graded in tone with brilliant backlit clouds.*

Exposure. Correct exposure is vitally important. Over-exposure eliminates the delicate nuances of tone between sky and cloud and gross over-exposure will even cancel out the effect of filters. The danger of over-exposure is greatest when photographing against the light, when clouds are brilliantly rim-lighted, but the landscape is usually in shadow.

Under-exposure has the opposite effect and increases contrast between cloud and sky by darkening the blue tones. This effect can be exploited either by choosing a foreground object which appears in silhouette, or by lighting the foreground subject with flash. The flash exposure is calculated so that the sky is under-exposed by about two stops. This expedient is also useful with colour film.

Clouds rarely stand still and 1/10 second is about the longest exposure that can be given safely.

In the darkroom, a slightly over-exposed sky can be darkened on the print by shading; if it has been heavily over-exposed, it may be reduced with persulphate reducer.

Excellent cloud effects—particularly at sunset—can be created by photographing straight against the sun when it is partly hidden or even slightly veiled by cloud or mist.

Very dark storm clouds which are not brighter but darker than blue sky present no problems. Normal photographic technique is all that is needed to reproduce them in their correct tones. Beautiful pictorial effects can also be obtained by waiting for the sun to break through holes in wind-driven storm clouds.

Printed-in-Clouds. Combination printing can be used to print in a good sky from another negative in place of an unsuitable or over-exposed one. In this case the lighting and cloud type in the sky negative should be chosen to match the subject conditions. Clouds can also be put in or reinforced by an air brush. H.W.

CLUBS AND ASSOCIATIONS

In 1852 the first photographic society in Britain was formed in Leeds. The second was the Photographic Society, now known as The Royal Photographic Society, founded on 20 January, 1853; other early societies include Liverpool Amateur Photographic Association on 9 March, 1853, and Dublin Photographic Society—now the Photographic Society of Ireland—which dates from 8 November, 1854.

Other societies in Europe which have enjoyed a continuous existence for over a century include the Société Française de Photographie (Paris, November, 1854); Manchester Photographic Society (November, 1855); Newcastle-upon-Tyne Photographic Society (December 1860); Edinburgh Photographic Society (1861); and the Photographische Gesellschaft, Vienna (1861).

The first affiliation of photographic societies took place in 1892. During the next few years there arose in different regions a desire to control their own activities more closely and in 1899 the Yorkshire Photographic Union was formed. This was followed by the formation of the present Northern Counties Photographic Federation in 1901; the Lancashire & Cheshire in 1905; the Midland Counties Photographic Federation in 1907; and the East Anglian Federation in 1910. During the complete reorganization in 1930 when the Photographic Alliance of Great Britain was formed to co-ordinate all the Federations, the old affiliation of photographic societies in areas outside the then existing federations was renamed the Central Association. It was by the transfer of clubs from this organization that the Western Counties Photographic Federation was formed in 1932; the Scottish Photographic Federation (originally founded in 1903) was consolidated in 1946; the Welsh Federation in 1951, the Northern Ireland Federation (later disbanded) in 1952, and the Overseas Federation in 1954. The Federation of Cinematographic Societies (later also disbanded) was admitted to the Photographic Alliance in 1937. The thirteenth member is the North and East Midlands Photographic Federation, admitted in 1955.

In April 1961 the right of automatic affiliation to the R.P.S., hitherto enjoyed by all clubs who joined their regional federations, was suspended and from that date all societies

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

accepted into membership by regional federations have been affiliated to the Photographic Alliance of Great Britain. The total number of clubs in affiliation in January 1964 was 1,163, but unaffiliated clubs probably number at least 1,500 more. The registered number of clubs in the Photographic Alliance, as given above, may be compared with the following approximate numbers in other countries in 1955: Denmark, 170: Federal Germany, 300: Italy, over 50: Japan, 1,500: Norway, 50: Sweden, 173: South Africa, over 40: U.S.A., estimated 1,500. In Russia there are no separate clubs as such.

Aims and Organization. The work of each club is determined by its aims, facilities, and space available at its headquarters. In the larger societies there are darkrooms, studio space and equipment, and libraries of photographic books and journals available. The officers and committee in almost every photographic body are re-elected annually by nomination and a secret ballot. In the majority of clubs the president or chairman serves for two years.

The annual or seasonal syllabus arranged in each society is usually planned to suit the majority of members and may include travel lectures illustrated by means of monochrome or colour transparencies, film strips or motion pictures; demonstrations of photographic processes and talks on technique and apparatus. A number of clubs organize brains trust meetings, jumble sales of unwanted equipment, displays of home-made articles, and one-man shows of prints and transparencies at every weekly or fortnightly meeting. Monthly competitions are also arranged, and there are annual exhibitions open to the public. Many clubs also arrange outings and rambles, when members' families and friends are always welcome. In large clubs the weekly meeting is usually devoted to some popular aspect of photographic work, while on other evenings of the week group meetings are arranged under the leadership of a specialist.

The address of the local photographic society in any district can be obtained from the local library, the area education office, a local photographic retailer, or the local newspaper. Or a letter to one of the national photographic journals will usually yield some information. There are also clubs which specialize in certain aspects of photography, such as natural history, architectural and stereoscopic work. Circulating postal portfolios are also popular with photographers unable to attend regular meetings.

Throughout Great Britain the average annual subscription is twenty-five to thirty shillings.

Federations. The services offered to members of societies are greatly extended when the club is affiliated to its regional federation. The subscription fees payable by the local club to the district association (whose committee is elected or appointed by all the member societies in that group) depend on the costs of the services expected by all the local societies in the federation to which they belong. In the Central Association, the largest in the United Kingdom and covering an area of some 7,000 square miles with an estimated population of over ten million, the membership fee is fifty shillings a year with a half-rate for junior clubs and schools. In return, the Association offers all its member societies over 90 lecturers with a choice of over 277 subjects, as well as 84 judges; through the other federations in the Photographic Alliance local clubs may also draw on another 400 lecturers with a further 1,000 talks and demonstrations plus the services of nearly 400 other judges and critics. The Photographic Alliance also offers affiliated clubs a large programme of recorded lectures with film strips or transparencies, loan collections of prints as well as slides, and a leaflet service on club management and club services.

Central Association members may participate in an annual exhibition, free of charge, from which the best entries are selected for submission to the annual national Photographic Alliance Exhibition.

BRITISH FEDERATION MEMBERSHIP

Federation	*Number of Societies*
Central Association	287
Midland	119
Lancs. and Cheshire	120
Scottish	113
Yorkshire	96
East Anglian	84
Western	52
Overseas	127

Welsh	46
North and East Midlands	62

The Central Association has encouraged the formation of small area organizations including Photograph Federations in Surrey; Kent; Hampshire and Wiltshire; South London and North West London, as well as the Berkshire, Buckinghamshire and Oxfordshire Association. Other groups operate in North London and West Sussex. Their activities are independent of the main body and their services include the organization of group club meetings to hear important speakers unable to visit every society in turn; inter-club competitions; regional annual displays and competitions; area conferences, and the compilation of lists giving the names of county judges and lecturers.

Founding a Club. The foundation of a new club in any district should only be contemplated when no other society exists within a reasonable distance; two or more bodies drawing on a restricted potential number of members in one community will only reduce the prestige, the strength, and the value of both organizations.

When, however, the establishment of a new society appears to be necessary, a preliminary meeting should be convened in an accessible public centre, preferably one which may

CC-0. Agamnigh Digital Preservation Foundation, Chandigarh

eventually serve as permanent headquarters. Town halls, church halls, libraries, local colleges or schools, professional or scientific centres, cafés, or private rooms in hotels may all be approached and considered. Notices advertising the purposes of the meeting would undoubtedly be displayed on request by chemists, photographic dealers, newsagents, libraries, and schools; an open letter to the local newspapers and the national photographic journals would also provide publicity.

After the meeting has approved the resolution that a photographic society be formed, a temporary committee should be appointed for the purpose of drafting the rules and fixing the subscription. The regulations should be as few as possible; the revenue should be as large as possible so that good facilities may be made available to members. The income must be calculated to cover rent, lighting, heating, subscriptions to the regional federation, and the purchase of equipment. Standard and miniature size projectors are most likely to be needed, as well as a screen, even if no further apparatus is required for demonstrations, darkrooms, and studios. The constant borrowing of equipment from members is to be strongly deprecated. Allowances may also be necessary for meeting lecturers' expenses, the cost of slide cabinets and print screens, an easel, blackboard and reading desk, stationery, postages, and many other incidental expenses depending entirely on local circumstances.

At the second meeting, members should be enrolled, the rules approved, a permanent committee appointed for a specified term, and a provisional programme of lectures announced. At first it may be difficult to fill a programme as many lecturers may have accepted engagements six months or more ahead. In such cases some of the trade organizations may be willing to assist by sending postal lectures which can be read by members; local dealers may also be invited to give a talk or demonstration at short notice.

If required, advice may be sought from the area federation or council, but it is not the duty of these unpaid officials and enthusiasts to nurse newly-formed clubs burdened with inexperienced or incompetent committees.

In every society the aim should be to make the legacy for future generations of photographers richer than the inheritance bequeathed from the past. Only through such a policy can photography become a force in the life of any nation.

COATED LENS. When light passes from air to glass, or from glass to air in a camera lens a small percentage is reflected back and where there are a considerable number of such surfaces the loss of light may become considerable. Perhaps more important than the loss of light is the fact that the reflected light, after possibly several internal reflections, eventually reaches the sensitive surface of the film in the camera as over-all light fog which has the effect of reducing the contrast.

Such reflection losses in a lens can be reduced by coating ("blooming") the lens with a thin, transparent film of, for example, magnesium fluoride. The coating should ideally satisfy two conditions: its refractive index must be such that light reflected from its upper (air-film) surface equals that reflected at its lower (film-glass) surface; its thickness must be such that the light reflected from its upper and lower surfaces cancels out (that is it is out of phase by half a wavelength).This gets rid of stray reflected light which normally degrades the photographic image.

The loss of light at any one surface for normal incidence is given by Fresnel as:

$$\left(\frac{N_1 - N_0}{N_1 + N_0}\right)^2$$

where N_0 is the refractive index of the first medium and N_1 of the second. Thus for a glass of refractive index 1·5 and air (refractive index 1) the loss is:—

$$\left(\frac{1{\cdot}5 - 1}{1{\cdot}5 + 1}\right)^2 = \left(\frac{{\cdot}5}{2{\cdot}5}\right)^2 = \frac{1}{25} \text{ or 4 per cent.}$$

Thus a lens system having six air-glass surfaces will transmit only about 78 per cent of incident light, 22 per cent being lost by reflection. This loss is not only undesirable because of the reduction in speed of the system, but also because much of the reflected light may reach

LENS COATING. Top: *A normal lens reflects and scatters light at each surface.* Bottom: *Coating largely prevents this loss.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

ELIMINATING REFLECTIONS. A surface film causes reflections at the air-film and film-glass interfaces. With the right film thickness, the reflected rays go out of phase and interfere (e.g., C and D for ray A, and D and E for ray B), cancelling each other out, thus eliminating the reflections.

the sensitized emulsion in the camera causing glare. However, if an air-glass surface is coated with a thin film of material whose refractive index lies between that of air and the glass, the reflection can be considerably reduced, and the transmission correspondingly increased.

For example, if a film of transparent material of refractive index N equal to 1·25 is deposited on the glass surface. Light will be reflected back at each surface of the film; these will be:—

$$\left(\frac{N_1 - N}{N_1 + N}\right)^2 + \left(\frac{N - N_0}{N + N_0}\right)^2$$

$$\left(\frac{1{\cdot}5 - 1{\cdot}25}{1{\cdot}5 + 1{\cdot}25}\right)^2 + \left(\frac{1{\cdot}25 - 1}{1{\cdot}25 + 1}\right)^2$$

$$= \left(\frac{{\cdot}25}{2{\cdot}75}\right)^2 + \left(\frac{{\cdot}25}{2{\cdot}25}\right)^2 = \frac{1}{121} + \frac{1}{81}$$

$$= \text{ say 2 per cent.}$$

This is the saving when the thickness of the film is uncontrolled. By making the film of suitable thickness and refractive index, the two reflected rays from the upper and lower surfaces of the film can be made to interfere so that for rays of normal incidence practically no light is lost by reflection and the energy so saved increases the transmitted light.

To fulfil this condition the refractive index of the coating should be the square root of the glass's index, and the film thickness should be one-quarter of the wavelength of the light for which extinction is required. Magnesium fluoride, having a refractive index of 1.39, nearly satisfies the first condition for most glasses, and its optical and mechanical stabilities are good; a lens system having six air-glass surfaces coated with this material may lose only 10 per cent of the incident light by reflection. The thickness of the coating is usually one-quarter of the wavelength of green light, and the less complete destructive interference in the red and blue ends of the spectrum result in the characteristic magenta hue of a bloomed surface. Surfaces which are coated to give minimum reflectivity of red and blue light show blue and amber colours respectively. While the reflected colour of a bloomed surface appears intense, the spectral transmission of a lens system is only slightly affected by coating. This slight effect is nevertheless sometimes used to balance the transmission characteristics of sets of interchangeable lenses.

To increase the mechanical stability of the thin film, the lens is frequently baked to about 250°C. prior to coating, and the resulting blooming is known as "hard".

While it is impossible to obtain complete extinction of reflected light of any wavelength with a single film on most glasses, this becomes possible with a combination of two films of different refractive indices and thicknesses. Components frequently used are bismuth oxide (refractive index 2·4) and magnesium fluoride. For minimum white-light reflectivity extinction of blue-green light is necessary owing to the assymmetry of the spectral transmission curve of a two-layer system. The resulting combination usually shows an amber colour by reflection. The use of two-layer blooming is particularly valuable in optical systems having many air-glass surfaces and in systems using monochromatic light, though for most purposes it has little advantage over a single film. A.W.S. (P.B.C.)

COBALT CHLORIDE. Used in certain metallic toners.

Formula and molecular weight: $CoCl_2.6H_2O$; 238.

Characteristics: Purple hygroscopic salt.

Solubility: About 80–90 parts in 100 parts of water at room temperature.

COHL, ÉMILE, 1857–1938. French caricaturist (real name: Emile Courtet). Produced in 1908 the first cine film consisting of animated drawings.

COINS. Collectors and numismatists often find it necessary to take photographs of coins and medals either to illustrate an article or a catalogue, or for normal records. Often an enlarged photograph of the coin, taken in suitable lighting, lends itself to examination more readily than the coin itself. Suitable photographs can be made with all the normal types of camera.

Equipment. There are three principal ways of tackling the subject depending upon the type of camera to be used. In each case, however, the most convenient arrangement is to mount the camera on a stand—e.g., in place of the enlarging head on an enlarger—so that it is looking down on the subject and can be easily set rigidly and squarely at any desired height from the easel.

Ordinary folding and box-type cameras do not extend far enough to be able to focus the

CC-0. Jangamwadi Math Collection. Digitized by eGangotri Preservation Foundation, Chandigarh

subject close up. The method here is to fit a supplementary lens in front of the camera lens. A lens of 12 to 18 ins. focal length is suitable for most work in this field. The camera focusing is set at infinity and the height of the camera is adjusted so that the lens/subject distance is exactly equal to the focal length of the supplementary. In this case there is no need to make any aperture correction. The camera lens must be stopped well down to compensate for the uncorrected supplementary lens.

Double or triple extension folding cameras present no difficulties. The height of the camera is simply adjusted until the image of the coin on the focusing screen is of the required size. The aperture of the lens must be corrected to allow for the close-up viewpoint.

Cameras with removable and interchangeable lenses—e.g., miniatures and single lens reflex cameras—can have the extension increased as necessary by extension tubes. Focusing in this case is done either by measurement or by focusing stage which allows a ground-glass screen to be substituted for the camera body while focusing the image. Here, too, the aperture value must be corrected for close-up working.

A further alternative is available with one or two of the classical miniatures. This takes the form of a copying stand which supports the camera at a fixed distance above the table and allows it to be used for close-ups with either extension tubes or supplementary lenses.

Lighting. Some form of spot-light directed almost horizontally across the surface of the coin from a distance of about 3 feet will bring out the relief. Flat lighting is useless.

The low angle of illumination naturally causes a shadow on the background at the far side of the specimen. This can be blocked out in the usual way on a large negative, but it is difficult with miniature negatives and in any case it is easier to avoid it altogether when making the exposure.

This is done by photographing all coins on a sheet of glass supported about eight to ten inches above the work-table. If white paper is then placed below the glass, the result will be a shadowless picture, and the coins appear to rest on nothing at all.

If it is desired to get a really black background, the best material to use is a special paper called flock paper. It has a short pile, a little like velvet, and it reflects almost no light. It is rather difficult to buy, but a dealer in fancy papers for display purposes should be able to obtain it.

Flaws. It is often necessary for certain details on a coin to be specially clear, for example, a line-flaw or the formation of a particular letter. Then the lighting must be carefully adjusted to show up the detail, while the image is watched on the focusing screen. To show a line-flaw clearly the light must strike the flaw broadside on. If the light is turned

SET-UP FOR COINS. The coin lies on a glass plate supported about 2 ins. above the enlarger baseboard. The camera is mounted on the enlarger column. A low spot lamp shining obliquely across the coin provides relief illumination to pick out the surface detail and inscriptions. At the same time it also illuminates the background.

through 90° from this position, the flaw will be almost invisible. It might happen that two such flaws occur at right-angles to one another. Here, if the light is directed on each at about 45°, it will make both flaws at least visible, though not so distinctly as in the case of the single flaw.

If the coin is of very bright metal which scatters the light, the image on the screen must be carefully watched while adjusting the light to cause the minimum scatter.

A polarizing filter is the ideal solution in such cases; the surface of the coin itself must not be dulled as this may easily ruin its "tone".

Exposure. The best advice for those who contemplate much coin photography is to standardize the set-up. Use the same lighting unit at a fixed distance and always work with the same fine-grain film and developer. Then the only things which will alter the exposure will be the amount of reduction and slight variations in the tone of the coins to be photographed.

Make a few trial exposures at various reductions with the lens at a fixed aperture and after making any necessary corrections, construct a table of exposures for each ratio of reduction likely to be used.

When using an extension to the lens for close-ups the *f* values for the particular lens do not hold good. These altered values can be calculated exactly, although the trial exposure method can be used quite satisfactorily by the more experienced.

As the exposures required may run to several seconds or even minutes, it is important to bear in mind the risk of reciprocity failure, particularly when using colour film. Thus, a theoretically correct exposure of 30 seconds may actually need to be increased to 60 seconds or more.

Depth of field is not a serious problem. Sufficient depth combined with the best defini-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

tion will usually be obtained with a good modern lens by stopping down about halfway. But when copying at natural size (1 : 1) or magnifying, it is best to stop right down.

Showing Both Sides. It is very desirable to show both sides of a coin side by side. Obviously two separate negatives can be taken, and the two negatives printed on the same sheet of paper. This will be the easiest method for most amateurs.

With a miniature camera taking 35 mm. film, there is a way of producing both sides of a coin on the one negative.

Choose a ratio of reduction so that the focused image can be made to occupy a little less than half the negative area and to lie close to one side of it. Make the exposure and wind on the next frame. Then turn the coin over, place it so that the new image is next to the frame previously exposed, and make the second exposure.

The film strip is afterwards cut up into normal-size frames by cutting through the middle of the frame so that the two sides of each coin appear side by side with a dividing line between them.

Using Casts. It is often necessary to reproduce both sides of several coins, all on one negative. The only successful way to do this is to use casts. These are made by taking impressions of both faces of the coins in wax from which plaster casts are subsequently made, one for each side.

Casts have so many advantages that they are used for the production of all the best photographic plates of coins, both in coin text-books and coin auction sale catalogues.

Among their advantages are: both sides of any number of coins can be taken together; as the casts are of a uniform colour the resulting photograph shows all the coins in a uniform tone; the original coins may have been unevenly toned or are badly stained, but the casts taken from them do not show these defects. C.W.P.

COLD CATHODE LAMP. Tubular fluorescent light source used principally in enlargers where its low working temperature is a great advantage. The tube is bent to form a grid which covers the whole negative area and gives such a uniformly distributed light that no condenser is required.

Cold cathode enlarger lighting is particularly suitable for plate sizes of quarter-plate and over, and the small amount of heat generated makes it possible to reduce the lamphouse to nothing more than a shallow box.

There are cold cathode attachments for fitting to the back of a plate camera to convert it into an enlarger.

One attraction of this form of enlarger illumination is that the light is principally composed of actinic rays so that the focused image and the image forming rays coincide more exactly than with a light of lower colour temperature. Another advantage exists in so far that condensers are not required to obtain even illumination, and so a range of different focal length lenses can be used in the enlarger without making adjustments or changes in the lamp housing.

The principal disadvantage of this light source is its high working voltage which calls for a special transformer.

See also: *Discharge lamp; Fluorescent lamp.*

COLD WEATHER. Weather around freezing point creates its own particular problems for the photographer. At the same time modern camera equipment is designed to stand up to a wide variety of climate and weather and generally speaking gives little cause for complaint in anything short of polar conditions.

Sluggish shutter action is the biggest problem in cold weather, but it is not likely to become noticeable until the temperature is several degrees below freezing point.

So this trouble rarely occurs in most of Britain, although it may call for attention in the north of Scotland. In parts of the Continent and in the mountainous areas everywhere, low temperatures are more common and may slow down the shutters of the best cameras. Even then the photographer will usually find that sluggishness begins only after the camera has been kept in the cold for a while.

Focal plane shutters are affected just as much as the diaphragm types. Fabric shutters are more likely to be affected than metal ones.

Some parts of the camera suffer more than others. The bellows may tend to harden at low temperatures and the only reliable way of keeping them flexible is to avoid leaving the camera extended in the cold air for longer than necessary.

Condensation. Condensation on the lens is one of the biggest nuisances in cold weather photography, especially in Britain and similarly humid climates. It is always wise to check the condition of the lens before using the camera and to wipe the lens gently if it shows any trace of moisture.

Condensation is apt to occur whenever warm, moist air comes into contact with a cold surface. It does not occur when cold air comes into contact with a warm surface. So the risk of condensation on the lens is always present when the camera is cold and is brought into contact with warm air. This means that a camera can safely be taken out into the cold air and no condensation will occur. But when it is returned to the case, slipped into the pocket or under the coat, or brought into a warm room, moisture may form on it. The next time it is taken out, the lens may be misted over and

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

incapable of recording a sharp picture. Wiping it gently with a piece of absorbent cloth or lens tissue is all that is needed.

When the camera is finally brought back indoors after a session out in the cold, moisture will again tend to form on it. This condensation will evaporate as the camera rises to room temperature, but until it does so, it should be left open in the warm air or it may remain damp after it is put away. A useful way is to place it in a tin with activated silica gel.

Fingers are a separate cold weather problem; anything that keeps them warm and alive is apt to impede their action. It is difficult to manipulate the camera when wearing thick gloves, but a pair of cotton gloves under wool mittens will usually solve the problem. This arrangement allows the fingers their freedom and provides a reasonable degree of warmth.

Camera. If the camera is kept in a warm-lined leather case it should remain in workable condition, even when the temperatures are low. If possible, carry the camera inside the overcoat or jacket until it is required for use. This precaution will ensure that the camera will be in good working order in the coldest weather likely to arise in the temperate climates.

A camera with an all-metal body chills more rapidly in cold weather than the conventional leather or plastic types and it is also more unpleasant to handle. For this reason, a wooden tripod is preferable to a metal one.

Although no one kind of camera is technically superior to any other for cold weather photography, the most practical is probably the twin-lens reflex; it is reasonably small and can therefore be carried quite easily under clothing; it is light—an important matter when walking on ice or in snow where after a while every item of equipment seems to increase in weight at every step. Furthermore, with a reflex camera there is no worry about exposed bellows and it can be manipulated quickly—a big factor in cold weather, when exposed fingers can quickly become stiff and painful. Finally the twin-lens reflex uses roll film which is by far the most convenient form of sensitive material for cold weather work. Some photographers do, however, prefer 35 mm. miniature cameras.

Sensitized Materials. Plates are not technically inferior to roll film for cold weather use, but films are easier to handle, lighter to carry and modern fine grain films are so good that for most purposes there is nothing to choose between the quality of an enlargement from a small film and the equivalent contact print from a plate negative.

Low temperatures have no ill effect on sensitized material, in fact very cold weather tends to preserve their qualities. Panchromatic materials are generally to be preferred to orthochromatic for cold weather photography because of their greater sensitivity to light in the red region, which is usually prominent when the sun is low in the winter sky.

Loading and unloading of films presents no serious snags in cold weather—so long as it is carried out under some form of shelter if there is any risk of powdered snow or ice being blown into the open camera by the wind. Generally it is enough to shield the camera with the body or under the coat. It is also important not to breathe on the back of the lens when changing the film. Film material gets brittle, and may snap if coiled too tightly.

Filters. Yellow filters are the most useful for the cold weather photographer. In snow scenes, in particular, the deep yellow filter assists in intensifying shadows in weak winter sunlight (thus giving greater contrast between snow and shadows) and emphasizing the brilliance of the snow. And a filter helps to improve the definition of distant scenery by cutting out the atmospheric haze so often present in winter landscapes.

As a correcting filter, the pale yellow or ultra-violet filter is ideal when exposures have to be kept short, but otherwise a medium yellow will be found to be of more general service. This yields abundant correction, sharply defines clouds, and gives a very close approximation to correct tone rendering. With panchromatic films a medium yellow filter requires only a two times increase in exposure.

Exposure. An exposure meter should always be used when working among snow and ice. Light values under such conditions can be extremely deceptive and are frequently very much stronger than they appear even if there is a lot of mist about. Moreover, the light can change quite rapidly. In snow scenes, when the sun is shining, the light can be so intense that it is beyond the range of the exposure meter.

At such times, it is advisable to stop down as much as possible, and it is as well to make sure that the lens diaphragm can be set to give a very small stop. (With many lenses the smallest stop allowed for is only *f* 16 which may be too large under such conditions.)

A lens hood is at all times an advantage, but when photographing snow or ice in sunshine it is absolutely essential if the negative is not to be fogged or degraded by stray reflected light.

Some of the most beautiful effects are obtained when one shoots against the sun; in fact, texture of snow can only be recorded this way.

Often it is wise to vary the exposure on either side of the meter reading because of deceptive light. Any serious photographer should budget for such multiple shots.

Low Temperature Development. Development should only be carried out at low temperatures when there is no alternative. Low temperatures give inconveniently long development times with practically all developers.

A high speed developer should be used to keep the development time as short as possible. The Kodak SD-22 formula is specially suitable for work at low temperatures:—

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Stock Solution A			
Sodium bisulphite	4	ounces	100 grams
Amidol	1	ounce	10 grams
Pyrocatechol	1½	ounces	40 grams
Benztriazole	35	grains	2 grams
Water to make	40	ounces	1,000 c.cm.
Stock Solution B			
Sodium hydroxide	5	ounces	125 grams
Potassium bromide	350	grains	20 grams
Potassium iodide	70	grains	4 grams
Water to make	40	ounces	1,000 c.cm.

For use take 1 part each of A and B, and 2 parts water. The mixture does not keep.

At temperatures below 0° C. an anti-freezing agent such as glycol must be used to stop the solution from freezing. The glycol may replace part or all of the water used in diluting the developer. The lowest useful development temperature under these conditions is about 0° F. (− 18° C.).

Fixing and Washing. As long as the solutions are above the freezing point of water, these operations should present no difficulty, as fixation and elimination of the fixer chemicals will still take place at quite low temperatures. The chemical action is of course slower, and longer times must be allowed.

To speed up fixation at low temperatures a rapid fixer based on ammonium thiosulphate may be used. A solution of ammonium thiocyanate is also very useful at temperatures below freezing; although in normal conditions it tends to frill the film.

At temperatures below 0° C., glycol may be added to the fixer to prevent freezing. The washing water may be treated similarly, but washing is best carried out in changes of water to reduce waste of glycol.

Drying takes considerably longer, too, and there is a risk of the water freezing on the film. To counteract this and to save time, the negatives may be soaked in 80 per cent methylated spirit (the colourless industrial variety) before drying. Before using this technique it is essential to check that the spirit contains no adulterant which is precipitated by the addition of water. D.L.

COLLEN, HENRY. Dates unknown. English miniature painter. Opened the first Calotype studio under licence from Talbot in Somerset Street, London, by August 1841. Used the Calotype chiefly as a base to paint on, and after a few years returned to miniature painting.

COLLODIO-BROMIDE OF SILVER EMULSION. Introduced by B. J. Sayce and W. B. Bolton, 1864, was the first workable photographic emulsion. It was a great step forward, for though somewhat slower than the wet collodion process, it had the advantage of dispensing with the inconvenience of dipping the plate in a sensitizing bath immediately before exposure. The collodion emulsion contained the more sensitive silver bromide in place of iodide, and tannin as a preservative. All the photographer had to do was to pour the sensitive emulsion on his glass plate. The commercial production of collodion emulsion dry plates was started by the Liverpool Dry Plate & Photographic Company early in 1867.

COLLODIO-CHLORIDE PAPER. Variety of printing out paper in which collodion replaces gelatin. It was popular in the middle of the last century.

See also: *Papers; Sensitized materials history.*

COLLODION. Transparent and viscous fluid used as the vehicle for the sensitive silver salts in the wet plate process. It consists of a solution of pyroxyl in equal parts of alcohol and ether. Also used for coating collodio-chloride (print-out) papers and for giving a high gloss (enamelling) to the surface of prints.

COLLODION PROCESS. The collodion (wet plate) process was invented by F. Scott Archer and published by him in 1851. It was in general use for 30 years, superseding the daguerreotype and calotype processes. Until recently, it was still used by process workers in photomechanical reproduction for making the negatives for line and half-tone blockmaking. In this particular industry, wet plates had a number of advantages: they have a very fine grain, good contrast, and they can be processed quickly and dried off by heat. They are also easy to intensify and reduce, but their sensitivity is low—only slightly faster than bromide paper.

To prepare them a clean glass plate is coated with collodion containing potassium and other iodides. It is then, in the darkroom, bathed in a solution of silver nitrate until the coating contains light sensitive silver iodide precipitate. The plate is exposed in the camera while it is still wet, and physically developed with a solution of ferrous sulphate and acetic acid, which reduces metallic silver from the silver nitrate solution on the wet plate, and deposits it on the latent image areas. Potassium or sodium cyanide is used for fixing and there are many methods of intensification and reduction by which very fine grain, thoroughly opaque and transparent line and half-tone images may be obtained—the cyanide solution can be washed out by merely rinsing under the tap for a minute; the hypo takes longer.

COLLOID. Name for any of that class of substances—e.g., albumen, caramel, glue and starch—which when dissolved in water will not diffuse through a parchment membrane. The colloids mentioned above are used in photography in various ways.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

COLLOTYPE. Photomechanical process invented by Poitevin in 1855 and perfected and commercially introduced by Joseph Albert in 1868.

It is still used for reproducing exceptionally delicate detail in monochrome and for short runs of a few thousand of colour work. It gives beautiful results with little perceptible grain structure.

A sheet of ground glass is coated with bichromated gelatin and dried in an oven so that the surface of the gelatin develops a reticulation grain of exceedingly fine wrinkles over the whole surface. After exposure to a continuous tone negative which selectively hardens the gelatin, and after a short general exposure through the back (hence the need for glass), the bichromate is washed out of the coating and the plate is treated with a solution of glycerine which renders it selectively hygroscopic in the less hardened areas.

The plate is then rolled up with a greasy lithographic ink which takes best in the areas containing the least water. This provides an ink image which is printed upon paper.

The main advantage of collotype is the minutely fine and asymmetrical nature of the reticulation grain which is excellent for reproducing delicate detail and, in particular, regular detail such as roof tiles, fabrics and the regular textures of geological specimens and steel engravings. These regular patterns tend to "clash" with a half-tone screen formation and produce an ugly interference pattern commonly known as "moiré".

COLOUR

Most people know that white light is a combination of all the other colours. A glass prism will split up a ray of white light into a pattern of coloured bands known as the spectrum, and under the right conditions, raindrops will do the same thing; the spectrum in this case is, of course, better known as a rainbow.

COLOUR AND VISION

The Spectrum. The colours of the spectrum are divided into bands of red, orange, yellow, green, blue, indigo, violet—in that order. These colours are visual sensations brought about by electro-magnetic waves of varying lengths. The wavelength is measured in Angstrom units; one Angstrom unit is equal to one ten-millionth of a millimetre and is usually written 1A.

Our eyes can see light of wavelengths between about 4,000 A—violet—and 7,000 A—red. Above and below this visible spectrum there are so-called invisible radiations—ultra-violet which has a shorter wavelength than violet, and infra-red which has a longer wavelength than red. But it is only the visible rays that have to be considered in normal colour photography.

Things appear coloured when they have the property of absorbing light of certain wavelengths and reflecting the remainder. When the mixture of coloured light making up white falls on a red geranium, the red light is reflected back and the blue and green light are absorbed and lost, so that the flower looks red because only the red light reaches our eyes. Blue glass looks blue because it allows only light of the short wavelengths to pass through it, the light of longer wavelengths (green and red) being absorbed.

How the Eye sees Colours. The human eye can be easily compared to a camera; it has a lens to produce the image, an iris for controlling its brightness, and it can bring objects at all distances into focus on the sensitive surface at the back of the eyeball. The sensitive surface, called the retina, is equipped with cells which are light-sensitive and correspond to the photographic emulsion. These receptors are of two main sorts, "rods" and "cones" (so called from their shapes). When an image falls upon them, they send impulses along the optic nerve to the brain which then experiences the sensation of sight.

Scientists do not yet agree about how we see in colour, but the theory that seems to fit the facts best is that the receptors form three separate systems. Each system responds to about one-third of the spectrum. One set reacts to violet and blue light, one to green and yellow, and one to orange and red. These divisions overlap so that, for example, yellow light stimulates a proportion of both the green and the red systems of receptors. The brain then interprets this joint message to mean yellow.

Again, when a beam of pure green light falls on a white screen, what we see is a green patch (for white reflects all colours), and with a pure red light we see a red patch. If both lights shine on the screen at the same time it will look yellow. According to the theory this is because both the green and the red receptors are stimulated, so that the brain receives impulses from both. As this is exactly what happens when we look at a yellow object, the theory fits the facts.

Effect of Viewing Conditions on Colours. The colour we see will depend on the lighting conditions of the scene as much as the actual colours of the scene.

The quality of the light, i.e., its spectral composition, will affect the colour—obvious examples are the sodium and mercury street lamps which are in common use today. The former give almost entirely yellow, while the

latter are entirely blue-green so that only those colours show. Less obvious is the distortion given by fluorescent lamps, which in many cases give light formed from a mixture of a few separate bands of wavelengths, not a continuous spectrum. Thus objects whose colour is in one of the gaps between these bands will appear darker and different in hue. There is also the difference between north sky light, sunshine, electric arc-lights and ordinary tungsten filament bulbs, which have progressively less blue and more red light respectively. This corresponds to a fall in colour temperature which alters the colours of the scene by making the yellow and red objects brighter at the expense of the blue ones and tends to make all the colours redder. The proportion of blue in sunshine can be changed by atmospheric haze or mist, which makes it more like the blue sky light, e.g., the blue haze on distant mountain scenery.

Another way of changing the light quality is by reflection, e.g., a subject against the background of a brick wall will actually be illuminated by reddish light because of reflection from the wall.

The intensity of the light will also affect the colours we see. Of the receptors, the cones only are colour sensitive and they function at normal intensities. At very low intensities, e.g., starlight, vision appears to be confined to the rods, which are colour blind. This explains the difficulty we have in discerning colours at night. It has the converse effect that a photograph in which the colours are dark and desaturated will look as if it had been taken at night, whereas one in which the colours are bright and saturated will give the effect of sunshine, although the exact opposite may be the truth.

Another factor which will modify the colour of an object is the direction of the light. If the lighting is very diffuse the colours will look desaturated and dull. This condition may be caused by an overcast sky or, even more noticeably, when this is combined with snow on the ground, or on the water. In these cases, light comes from all angles and, even though the actual intensity may be high enough to give the normal "cone" vision, the desaturation effect occurs.

On the other hand if the light is strongly directional, e.g., full sunshine, the colours will appear at their brightest, particularly if the surface is glossy and reflects well. Thus wet patches on matte objects will appear brighter than the dry parts. The actual reflections of the light source are not coloured; since the light is completely reflected from the surface, none is absorbed by the object, which therefore appears the same colour as the light source itself. This explains why the highlights, on the eyes in portraits, for instance, or on ripples on water, etc., are always white.

The eye is also capable of adapting itself to different colours of illumination. It is well known that on coming out of sunlight electric light appears yellow since the eye is adapted to the white of daylight which is relatively more blue. After a few seconds, however, the eye adapts to the new type of light and is quite satisfied that this is white. Similarly, on projection of transparencies or cine film in a darkened room, the eye will adapt to the overall colour balance of the picture. Thus pictures which are out of balance and would appear to have an objectionable colour cast when viewed by full daylight will often be quite acceptable when projected.

Colour and Contrast. Yet another factor which modifies the colours we see is the contrast of an object with its surroundings. If we take two identical patches of colour and surround one with a black border and the other with a white, the former will appear both lighter and brighter (more saturated) than the latter. The same thing happens if the borders are the same hue but a darker or lighter shade respectively. This is a well known optical illusion; it is shown very clearly in step-wedges. Where steps of increasing density adjoin each other, one edge of the step will appear lighter in contrast with the darker neighbour and the other edge will appear darker so that the density appears to vary across the step. This occurs in neutral black-and-white wedges but can be very noticeable in coloured ones.

A similar effect is that of colour contrast. A colour will always appear brighter when it is viewed against a background of its complementary colour and if subject and background are not of complementary colours, the eye will tend to see them as if they were. This can be shown more plainly if we consider green foliage against a grey wall; if the foliage is a good saturated green, the wall will appear pinky-grey because the colour balance of the eye is adapting towards green so that other objects become magenta by comparison.

Subjective and Objective Colour. In colour photography the eye tends to see what it wants to see, whereas the film sees what is actually present. Thus, in the example of the subject next to a brick wall mentioned above, the film would record the subject as much more red than it really was because of the increase of red in the light by reflection from the wall. But this might pass unnoticed by the photographer for two reasons. First, the eye will adapt itself to the new colour of the light so that the reddish light will now appear white. Secondly, even if full adaption does not take place, the brain will still reject the findings of the eye if they do not fit in with what it knows to be true. Thus we shall think we see correct flesh colours on the subject's face even if the eye is sending a message along the optic nerve that the face is red. These psychological effects are most persistent and any scene will be compared in the memory with an average of what that scene should look like and different findings by the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

eye are ignored. This often gives rise to big differences between photographs showing the scene as it really was and memory fitting it to agree with what the brain thinks it ought to have been.

Similarly there are associations of colours with other feelings—red colours with warmth, blue with cold, etc., and these too can operate in reverse so that a warm room will appear redder than it is, a cold scene bluer. In the same way red colours are advancing, blue colours receding tones so that distant objects may appear bluer than they really are or conversely, a blue object in a picture will look farther away. There are many of these psychological effects which change the colours we see, or think we see, but do not, of course, change the physical reality seen by the camera itself. J.Mo.

COLOUR HARMONY

When a presentation of two or more concurrent colour stimuli typically affords a pleasing impression, there is colour harmony. More strictly, colour harmony refers to the pleasingness of the combination itself, over and above any favourable effect of the components taken separately. This harmony of the combination itself seems more stable and fundamental than the liking for colours taken separately, and so the distinction is of some importance. Common usage, however, ignores the significance of the combination as a unit, and simply correlates colour harmony with over-all pleasingness.

Criterions. Everyone sees colour arrangements which he personally likes or dislikes, but colour harmony is more than a mere matter of individual taste. Though necessarily based on personal preference, colour harmony is conceived as a social phenomenon which is subject to statistical and experimental test; only if enough qualified people like an arrangement is it to be regarded as really harmonious. "Qualified people", according to the older view, comprised a relatively small group of acknowledged experts; according to the newer view, the contemporary population in general. Thus the consensus of the group provides the criterion of colour harmony.

Great difficulty has been encountered, however, in establishing the subject of colour harmony on a dependable basis. Despite the many outstanding artistic contributions through the ages, it would be possible even today for any colourist to pose with the public as a colour harmony expert and promote almost any general collection of colour samples of possibly completely haphazard relationship as a system of colour harmony.

This state of affairs is readily understandable in view of the many variables involved and the many different combinations which can afford colour effects which are at least acceptable. Moreover, aesthetic preferences themselves are so often slight, doubtful, or even lacking, that serious objections to a confident recommendation are unlikely. The general picture is complicated by variations to be expected in different times and places due to differences in personalities, colour fashions, customs, cultures, national and local traditions, and ethnic groups.

Probably the greatest difficulty is one which has only recently been removed, that is, inability to control colour stimuli closely enough; for unless various combinations can be produced and reproduced in various settings, the experimental investigator cannot verify his findings or even know what he is working with. But this unsatisfactory situation is improving significantly and may eventually be eliminated now that effective experimentation is feasible.

In the meanwhile, there are various technical groups such as artists, decorators, architects, industrial designers, lighting engineers, and photographers who are becoming increasingly concerned with the production and control of colour harmony. They have at their disposal a considerable accumulation of aesthetic rules and precautions which have gradually accumulated through the centuries and which are beginning to feel the impact of scientific corrections. Restrained use of traditional precepts, as in choosing arrangements for preliminary check viewing or getting a point of departure, can be effective.

If something exceptionally good is hit upon, a careful record of the circumstances can be made for future reference. By trial and error, an effective repertoire may be developed. Following is a summary of the more persistent older precepts, and also more recent developments.

Single Colours in Isolation. Colours which are pleasing separately tend to be pleasing in combination. Taken separately and on the average, red and blue are the most pleasing hues, while yellow and orange are the least pleasing. Within limits, increasing the lightness of a colour increases its pleasingness, and similarly for saturation. A minority group prefers relatively weak, desaturated colours. Colour space is marked by limited regions rather than sharp points of preference.

Continued contemplation of a colour sample tends to produce affective adaptation—i.e., reduction in pleasantness or unpleasantness toward indifference. In closely successive viewing, affective contrast may either increase or decrease pleasantness, depending on the direction of the contrast. Preference for particular colours is affected by age, fashion, and other factors. Colour preferences vary more between individuals than within individuals.

Combinations of Colours. In regard to binary combinations, large or small rather than moderate hue differences harmonize best. According to this, for example, a neck tie of

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

yellow or greenish-blue (but not green) would go with a blue shirt. Experiment confirms that harmony increases with increased hue difference. Reference to Rood's hue circle is helpful in visualizing hue intervals. Complementaries are located in the hue circle about opposite each other—i.e., at maximum hue interval. They can be readily paired by reading off the colours at the opposite ends of a double-headed arrow. Exact complementaries, however, seem no more harmonious than nearby hues.

High contrast in either saturation or brightness is harsh and likely to produce dazzle or flutter; complementaries harmonize best when one or both are unsaturated. (The recommendation that triads or triple colours be equi-spaced in hue, can be followed by using a triple-armed pointer on the Rood's circle.) Complementaries may be combined with related colours and two pairs of complementaries are sometimes used together. Other "four-colour harmonies" and still more complex combinations have been endorsed. The more complex hue combinations depend greatly on effective use of saturation and brightness. In regard to aesthetic balance, strong saturation is best restricted to small areas. Large areas of weak saturation balance small areas of strong saturation; the same thing happens with lightness. Saturation and lightness have been combined in a single balance formula.

Designs and Decorations. Colour contributes to other aesthetic factors, and the more complex a design or composition the greater this contribution can be. Thus colour can be used to simplify by obscuring irregularities, as with paint; and colour can contribute to aesthetic unity by employing a dominant hue, or an extended background, or repetition. Contrasting colour can place desirable accent on regions of special interest. Lightness variation can avoid vagueness or monotony, especially in monochrome designs. Colour can contribute to mood as by subtle textural effects and modes of appearance. Dominantly warm colours in a composition create a warm impression, and dominantly cool colours create a cool impression. Dark colours are suggestive of greater weight, light colours of space.

The natural lightnesses of colours are considered safest, for instance, light for yellow and dark for purple-blue. Moreover, the pleasing colour complexes of nature may persist or even actually improve in pictorial conditions, but they are not dependable for human designs.

Over-all pleasingness often depends greatly on appropriateness or suitability in relation to function; for example, a painted industrial machine is more satisfactory if the colour contrasts are arranged to minimize fatigue, or a decorative poster is more agreeably informative if it is legible. More general environmental harmonies are achieved by colour co-ordination of larger units such as work rooms, whole interiors and exteriors, aeroplanes, trains, and housing developments.

Though many of the present available rules and precepts are helpful, they are too simple and specific to apply unreservedly to designs of complexity. There are signs that more adequate, higher-order principles of colour harmony may eventually be discovered.

Of recent years the general public have begun to take a greatly increased interest in colour. This naturally results in broader and more discriminating colour perceptions, more critical demands for adequate colour systems, and a greater sensitivity to colour harmonies and discords. These developments tend to stimulate progress in colour photography S.M.N.

Book: *Interaction of Colour*, by J. Albers (Yale); *Eye, Film and Camera in Colour Photography*, by R. M. Evans (New York).

COLOUR CAMERA. Special "one-shot" cameras used to be manufactured in which all three separation negatives were exposed at the same time. These cameras incorporated partially silvered reflectors in the camera between the lens and the focal planes. In one-shot cameras for still photography, the image forming rays, after passing through the lens, were split up into three parts by a system of mirrors or membranes called pellicles. Each part was focused through a suitable tri-colour filter on to a separate plate (or film). The filters were located immediately in front of the plates. The three plates were then developed to make the separation negatives. One-shot colour cameras have now become obsolete owing to the ease with which colour transparency and colour negative films yield direct colour prints.

Many designs have been proposed for one-shot colour cameras, but the types that have been commercially available are all of a few similar basic designs. All the cameras are of necessity somewhat bulky and cumbersome. There are three types of light-splitting systems: semi-silvered mirrors, pellicles, and prisms. Systems of the latter type are still used in colour television cameras.

Splitting Systems. Glass mirrors have the disadvantage that they refract the light passing through them so tend to distort the image. Also, they give a double reflection from the rear surface of the glass.

So almost all one-shot cameras for still photography used pellicle reflectors—very thin sheets of collodion or cellulose, less than one-thousandth of an inch thick. These were stretched across optically flat metal frames. Pellicles were so thin that they eliminated the

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

COLOUR BACK. This single-exposure unit fits on the back of a normal camera. A single mirror deflects part of the light to a bipack B and G, the rest forms the red record R.

risk of double reflection and refraction. The pellicles were coated with a metallic layer to obtain a suitable reflection-transmission ratio.

The principal design of still colour cameras took three separate plates and had two pellicle reflectors, each of which reflected part of the light and transmitted the rest. The rays of light from the lens fell on the first reflector which deflected roughly one-third on to the blue record plate and allowed the remaining two-thirds to pass through it to fall on the second mirror. This mirror deflected roughly half of the remaining light on to the red record plate and allowed the other half to pass through to the green record plate. Each of the plates was mounted at the correct focal distance from the lens so that sharp images of identical size were formed on all three.

Another design of one-shot camera used a single reflector and had only two focal planes. In this type of camera, one of the negatives was made on a single film in one dark slide, and the other two negatives exposed on two special films loaded in the other darkslide together face to face in the form of a bipack. For example, the front film of the bipack might give the blue filter record, and the rear film the red filter record, both being in the reflected beam in the camera. The green filter record was then given by the single film in the transmitted beam in the camera.

DOUBLE MIRROR COLOUR CAMERA. The first mirror deflects about one-third of the light to the blue record plate B behind a blue filter, the second mirror divides the remainder between the plate behind a red filter R and one behind a green filter G.

The relative simplicity of a single mirror camera led to the introduction of many models of this type for still photography until manufacture of the special bipack film was discontinued.

Prism-reflecting systems have been used in certain miniature size one-shot cameras, but the weight and expense of prisms preclude their use for larger negative sizes.

Prism type reflectors were also used in one-shot motion picture cameras, which have a single reflecting surface and two film gates, using a pair of films as a bipack in one gate, and the third film in the other.

Construction. It was usual for the camera body to be made of metal since the three separate images must stay in accurate register with each other. Any differences in the size of the images would produce colour fringes in the finished positive.

The reflectors and plateholders were almost always mounted in a rigid housing with the lens on a separate rack-out panel joined to the body by bellows. The shutter must be mounted on or near the lens so that it cuts off the light before reflection. For this reason focal plane shutters would be impractical in a colour camera.

Few camera movements were provided on one-shot colour cameras. Some designs provided for rising and cross fronts and sometimes for swinging the lens. But a swing back was never provided because of the obvious difficulty of swinging each of the plateholders exactly the same degree to maintain perfect register of the three images.

The lens for a colour camera must naturally be well corrected to give the three colour record images of equal size and sharpness. Smaller cameras used first-class anastigmat lenses, but larger cameras generally used the more highly corrected apochromatic lenses for optimum image quality.

The most popular formats were quarter-plate to 4 × 5 ins. for professionals and $2\frac{1}{2} \times 3\frac{1}{2}$ ins. for amateurs and for use in the hand. Some 5 × 7 ins. cameras were made for portrait and commercial studio work.

Sensitized Material. Most one-shot colour cameras were made to take plates or sheet film. Normally panchromatic emulsions of the same type were used in all three darkslides. Some makes used one panchromatic and two orthochromatic emulsions, or one panchromatic, one orthochromatic, and one (blue non-colour sensitized) sensitive plate.

Usually the exact sensitive material employed in a colour camera depended on the filters fitted and the metallizing of the reflectors, and the camera manufacturer specified a suitable sensitive material and quoted a film speed to be used for his camera-film-filter combination as a whole. A.P.J.

COLOUR CORRECTION OF LENSES. Elimination of lens aberrations with reference to the reduction of faults varying with the wavelength of light. In popular photographic advertising lenses are frequently referred to as "colour corrected" to imply to their suitability for colour photography.

In fact colour correction of a lens is as important in black-and-white photography as in colour. The principal faults—several kinds of chromatic aberration—lead to a different plane of sharpness or to a different image scale (or both) for images formed by light rays of different wavelengths. In a colour photograph that may produce colour fringes and loss of definition; in a black-and-white negative made on panchromatic film the same loss of definition will occur and reduce the detail resolution and the detail contrast of the image. Lenses without colour correction would be suitable only for photography by light of a single wavelength.

Types of Colour Correction. Chromatic aberrations are corrected by combining lens elements of different dispersion so that the colour errors introduced by the individual elements cancel out. In a simple form achromatic correction makes the position and size of images coincide at two specified (and usually well-separated) wavelengths of the spectrum. This yields an acceptable compromise over the whole spectrum range, but does not necessarily correct all intermediate colours. When using certain colour filters the plane of sharpest focus may therefore shift slightly. This is one of the reasons why for maximum accuracy the image should be focused through the filter through which the exposure is made. (Another reason is that the filter may, through its actual thickness of glass, introduce slight image shifts.)

With apochromatic correction the lens is corrected for three main spectral regions. Such lenses are essential in graphic arts and colour separation work for exact registration of images corresponding to different colours.

Infra-red and Ultra-violet. Neither achromatic nor—usually—apochromatic correction covers radiations outside the visible band. Thus the image formed by ultra-violet or by infra-red rays may not be formed in the same plane as a visible image. Photographs under conditions where the prevailing light is rich in ultra-violet rays (for example alpine views) are therefore liable to show some loss of definition. An ultra-violet absorbing filter remedies this.

For pictures to be made by ultra-violet or infra-red rays exclusively, the visual and the photographic foci do not usually coincide. Hence after focusing visually the lens requires resetting to reduce its distance from the image plane (with ultra-violet radiation) or to increase this distance (for infra-red photography). Some lenses carry a second setting index for focusing with infra-red rays (since visual focusing through a nearly opaque infra-red transmitting filter is virtually impossible). Ultra-violet photography is only possible with lenses specially designed for the purpose, which have appropriate ultra-violet transmission characteristics. Such lenses may have a distance setting scale calculated for a particular wavelength of ultra-violet rays.

Colour Correction and Colour Rendering. The glass elements of the lens itself may have certain absorption characteristics which can affect the colour rendering of a picture taken through that lens on colour film. A lens which absorbs ultra-violet rays strongly (and possibly even some light of the extreme violet end of the spectrum) yields a warmer (slightly more reddish) colour rendering than a lens of less pronounced ultra-violet absorption. Hence colour pictures taken with different cameras are unlikely to show exactly the same colour balance even discounting other variables.

In practice this is disturbing only when a range of interchangeable lenses is used with a given camera. The variations in colour rendering then show up when a complete set of colour transparencies is projected in succession. Some lens manufacturers match lenses of an interchangeable series belonging to the same camera by a suitable choice of lens coatings. For a lens of maximum ultra-violet absorption the coating may be virtually non-absorbing in this spectral band, while lenses of lesser absorption may receive a coating that itself holds back some ultra-violet radiation. Appropriate balancing of these coatings then yields consistent colour rendering throughout the range of lenses. L.A.M.

COLOUR FILM PRINCIPLES

The basic principles of colour reproduction are described in this section. In order to illustrate these principles clearly, the discussion concentrates on subtractive reversal colour films. These are the films which produce the majority of positive transparencies for viewing in projectors.

Colour negative films and their associated colour print materials involve the same principles as reversal films. Their only difference is in the detailed processing to a final positive image, and the fact that the final image is a print instead of a transparency. Some of the more important differences between negative and reversal materials are pointed out at the end of this section.

Additive colour photography is not discussed here in any detail as this is now used only for specialized purposes, for instance, in colour television.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Integral Tripack Colour Films. Nearly all modern colour reproduction processes rely on the fact that red, green and blue light can be combined to produce a wide gamut of colours. In subtractive colour photography the proportions of these three colours in the original scene are recorded as latent images on three suitably chosen emulsions. These latent images are used to control the development of three dye images, and these dyes control the amounts of red, green and blue light projected onto the screen. The three dyes used must be superimposed, so in the film the three recording layers are situated one on top of the other on the same support (hence the name integral tripack). In principle then we need three dyes, each of which absorbs light throughout (roughly) one third (i.e. red, green or blue part) of the spectrum and transmits freely elsewhere, together with three emulsions, each sensitive to one third of the spectrum only.

All silver halide emulsions are basically sensitive to blue light. In order to make an emulsion react to green light alone the emulsion must first be made sensitive to green light by optical sensitization and then, as it still retains its blue sensitivity, it must be used behind a filter that absorbs blue light. Similarly an emulsion sensitive only to red light must be optically sensitized to red light and again used with a blue absorbing filter. The tripack colour film can then be made up, with three sensitized emulsion layers and a filter layer: the top layer is sensitive only to blue light; below this is a yellow filter layer to absorb blue light, and below this again are the green and red sensitive layers. Conventionally the red layer is at the bottom of the tripack next to the support, or base. (Other layers may be added to this basic arrangement but they are refinements which need not concern us here). Despite this stack of emulsion layers, the overall thickness of the tripack is only about 0·0005–0·001 in., and the base about 0·003–0·005 in. thick.

The choice of filter layer, optical sensitizers and emulsions requires great care. The filter layer should be capable of absorbing all the blue light to which the "green" and "red" emulsions are sensitive, but should let through all the green and red light. The green and red optical sensitizers must be chosen to give sufficient sensitivity to these colours so that all three layers are effectively the same speed, but they should not overlap in their sensitivities otherwise colour reproduction is impaired. Further, the three sensitivities should combine to cover the whole of the visible spectrum.

The three layers must not only be balanced for speed but they must also be balanced for contrast and general characteristic curve shape. The emulsions must therefore be carefully chosen to meet these and other requirements, such as balance of reciprocity failure and latent image effects, and to give good graininess and sharpness properties.

In practice not all of these requirements can be met. The filter layer lets through some blue light, which impairs colour reproduction, and absorbs some green and red light, which reduces the effective speed of the green and red layers. Due allowance of this must be made when sensitizing these layers. No set of sensitized emulsions exist which give no overlap of sensitivities for the three layers and cover the whole spectrum uniformly. The sensitivities used have to be a compromise—with some overlap and some non-uniformity of coverage.

The particular form of the sensitivities chosen will of course play a considerable part in the quality of colour reproduction of the film. These chosen sensitivities will match only one particular type of illuminant, say daylight. If the energy distribution of the source is changed, say by using tungsten light, the effective sensitivities of the three layers will no longer match each other. The film will not therefore be balanced and will reproduce colours with a strong colour cast (yellow-red in this case). Similar balance changes can occur if the amount of ultra-violet light changes. Here the camera lens is important as some lenses absorb considerably in the ultra-violet region of the spectrum. The film manufacturers try to match film sensitivities in relation to an average lens but it remains that lenses vary over a considerable range in this respect.

Exposure and Development. Just what happens during the exposure and development stages of a colour reversal film may be illustrated by considering four patches—white, green, magenta (purplish-red) and black. When the film is exposed, light from the white patch affects all three emulsion layers—that is, a latent image is formed in each layer. The light from the green patch will produce a latent image in the green layer alone; light from the magenta patch will produce latent images in the blue and red layers (magenta being a combination of red and blue), and the black patch does not emit light so it will give no latent image in the film.

The film is then processed first in a black-and-white developer to produce a negative exactly as in ordinary monochrome films. The dyes are then developed up in their appropriate layers, using the silver halide remaining after the first development. Yellow (blue-absorbing) dye is developed in the blue layer; magenta (green-absorbing) dye in the green layer, and cyan, or blue-green (red-absorbing) dye in the red layer. The film is then bleached and fixed to remove the unwanted silver image and the yellow colour of the filter layer, leaving just the three-dye image.

Let us now consider the dye images for the four colours, white, green, magenta and black. For the white patch all layers were exposed and developed in the black-and-white develo-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

REVERSAL COLOUR FILM PROCESSING. 1. Subject consisting of blue B, green G, red R, white W, and black B. 2. Exposure produces latent images in the layers sensitive to the different colours. 3. First development yields a negative silver image. 4. After re-exposure, second development produces a positive silver image together with a positive dye image. 5. After removal of all the silver by bleaching and fixing, only the positive dye image is left.

per so that no dyes are developed up. With no dyes present all the light from the projector is transmitted onto the screen and therefore appears as a white patch.

Similarly for the green patch, yellow and cyan dyes are present so that the blue and red components of the projector light are absorbed and only the green component is transmitted onto the screen. For the magenta patch, the magenta dye absorbs green light and red and blue are transmitted. Finally, for the black patch, all three dyes are present so that all the projector light is absorbed and none is transmitted to the screen.

Substantive and Non-Substantive Process. The process by which the dyes are introduced into the film during development may take one of two forms.

In the first procedure, referred to as a substantive colour former process, the three dye colour formers are introduced into the film in their appropriate layers during manufacture of the film. In processing, the film is re-exposed, after black-and-white development, to white light to render the remaining silver halide developable and then the film is colour developed—the developer reacting with each of the three colour formers to produce the appropriate dye.

In the second system, the non-substantive colour former process, the dye formers are contained in the developer solution itself, and a different solution is used for each dye. The normal sequence in processing is similar up to the end of the black-and-white development of the negative image. Then follows a selective re-exposure of the red layer alone and development in a cyan colour developer. The blue layer is then similarly treated by selective re-exposure (from the top of the film so that the filter layer prevents exposure of the green layer) and development in a yellow colour developer. Finally the green layer is re-exposed and magenta colour developed.

Each process has advantages and disadvantages. Substantive films are complicated to manufacture but relatively simple to process (this type of film can often be home processed). The processing of non-substantive films is more complex but their manufacture is relatively straightforward, at least by colour film standards.

Safelights. Generally safelights are not recommended when processing colour film. If these are necessary on any occasion, a study of the spectral sensitivity curves shows that films are least sensitive in the blue-green and the yellow regions of the spectrum. At low illumination levels the eye is most sensitive in the blue-green region so the best safelight filter would be a narrow-cut blue-green filter matched in its particular characteristics to the film being used. The overall illumination level must still be kept very low even with this filter in use and is suitable only for checking a darkroom clock, or for finding equipment in the room, but not for judging the appearance of the developing image on the film.

SPECTRAL SENSITIVITIES. The sensitivities shown for the blue (B), green (G), and red (R) recording layers are typical for a reversal colour film balanced for daylight use. The blue recording layer is sensitive well into the ultra-violet region, far below the limit of the eye.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

SPECTRAL ABSORPTION CURVES. These curves are typical of image dyes used in reversal colour films. Top: *All three dyes together, if divided in the appropriate proportions, should yield a visual neutral or grey (dotted curve).* Bottom: *Addition of yellow and cyan (Y, C) produces green (dotted curve).*

Image Dye Characteristics. The three dyes used to form the image are cyan (blue-green), magenta and yellow. These absorb respectively red, green and blue light. Spectral absorption curves for a typical set of these dyes show that the dyes are "imperfect" in that their absorption bands overlap and they do not absorb uniformly in their appropriate regions. (Absorption here is expressed in terms of density, D, where $D = \log {}^{1}/_{T}$, and T is the ratio of transmitted to incident light—the transmission). The amount of each dye that is produced to form the image depends upon the original exposure. Where the silver halide in the emulsion is completely exposed, no dye will form; where no silver halide is exposed, a maximum amount of dye will form, and there is a steady gradation between these two extremes for steadily changing exposures. The spectral absorption curves of varying amounts of dye are well defined since the density at any wavelength is proportional to the amount of dye present, e.g. doubling the amount of dye will double the density at each wavelength.

The film manufacturer tries to reduce the overlap, or unwanted absorption, of the dyes in order to obtain "clean" colour reproduction, but there is a limit to what can be done in this direction. Generally dyes which do not give significant unwanted absorption are also very "peaky"; that is, each dye only absorbs heavily over a narrow region of the spectrum. If three such peaky dyes were used then there would be nothing to absorb light between their peak absorption regions (in the blue-green and the yellow regions of the spectrum). Consequently some greenish-coloured light would always reach the screen even with the maximum amounts of all dyes present, in other words it would not be possible to reproduce good blacks and dark colours. Again then the manufacturer is forced to a compromise in the choice of dyes in order to produce good overall colour rendering.

An interesting effect is that the dyes used to produce a grey colour (visual neutral) do not give uniform absorption throughout the spectrum. This means that if the colour of the illuminant is changed then the "grey" patch may no longer look grey. One of the important criteria in all colour reproduction is that greys in the original scene should be reproduced as greys. This is referred to as the colour balance criterion. (A film which is out of balance is one where greys are not correctly reproduced and the whole picture appears to be tinted). The manufacturer aims to produce a correctly balanced transparency for its appropriate illuminant, namely projector light, and attempts to choose dyes so that the transparency also appears to be in balance when viewed in daylight (as such viewing conditions are often used with, for example, hand viewers).

Sensitometric Curves. As in black-and-white photography properties such as speed and contrast may be determined by exposing the film to a range of intensities of light and measuring the densities of the images produced. The standard exposing light is a "white" light, and a range of intensities of this light produce a grey scale. A graph of density against the logarithm of the exposure (log E) yields the characteristic curve of the material. In black-and-white photography the characteristic curve is easily obtained as the density is produced by a single silver image. In colour photography the image is made up from three dyes so it is necessary to make three density measurements. These measurements are made in the red, green and blue regions of the spectrum. The density in the red region of the spectrum will depend mainly on the amount of cyan dye present, the green density depends mainly on the magenta dye, and the blue density depends mainly on the yellow dye.

A grey scale characteristic curve for a colour film in fact consists of three curves, one for each layer. In order to simplify their assessment the densitometry is so arranged that the three densities are equal for a true grey. The relative positions of the three curves then indicate the amount by which the film is out of balance at any point. For example in the maximum density region of the curves the red density may be low and the blue high. This indicates a lack of cyan dye (therefore too much red light is trans-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

mitted) and an excess of yellow dye (too much blue light is absorbed). The maximum density will therefore appear yellowish-red.

Speed and contrast can be measured as in black-and-white photography—the speed is determined by the relative position on the log E axis and the slope of the straight-line part of the curve gives the contrast. The manufacturer can measure these various properties from the characteristic curve and from them can make any necessary adjustments to the film or the development. Similarly any processing station, or individual with the necessary facilities for measurement, can control development to a high order of accuracy.

For a full sensitometric assessment of colour films in addition to a grey scale exposure it is necessary to examine saturated and desaturated red, green, blue, cyan, magenta and yellow scale exposures. These exposure scales are used mainly by the manufacturer. From them it is possible to detect, amongst other things, any spurious development of dyes in wrong layers and whether or not any unusual interlayer effects are occurring.

Other Colour Measurements. Density measurements of colour as just described are of relatively limited use. In order to study the general properties of colour reproduction of a film it is necessary to make much more detailed measurements.

CHARACTERISTIC CURVES OF REVERSAL FILM. Top: *For a visual neutral the curves should be superimposed. This composite curve is used to determine the mean contrast, speed and balance of the film. The solid curve corresponds to the green densities (i.e. magenta dye measured through a green filter), the broken curve to red densities and the dotted curve to blue densities.* Bottom: *Green scale characteristic curve corresponding to the reproduction of a saturated green colour at varying exposure levels. At very low exposures the film reproduces greens as near grey due to the limit of maximum density. Excessive exposure also leads to poor reproduction.*

A further example of the use of subjective colour measurements is in the study of the variation of saturation with luminosity. For instance in a green scale characteristic curve, the three curves converge as the exposure decreases, this indicates that the saturation of the green decreases and eventually becomes zero (a grey). An underexposed transparency will not then yield well-saturated colours. A similar effect can also occur for overexposed transparencies.

An example of the use of objective measurements is the examination of the chromaticity gamut of a set of dyes, on a C.I.E. chromaticity diagram. This gamut is very much compressed and distorted compared with the gamut of real colours. The compression can be offset to some extent in practice by using a fairly high contrast for the film, but the distortions are much more difficult to overcome. Generally the manufacturer aims to produce a pleasing reproduction—one in which the more important colours such as flesh tones, grass and sky are not obviously wrong.

Colour measurements must always be very carefully interpreted to be meaningful. In colour photography such measurements are further complicated by, for example, the fact that a scene originally viewed in daylight is viewed in reproduced form in projector light, and the fact that the "memory colour" of, say, flesh tones may not be the same as the colour observed in the original scene.

Colour Negative Processes. It is possible to make colour prints from colour transparencies but when colour prints are required it is easier and more economical to print from colour negatives.

The processing of negatives differs from transparencies in that there is only one development stage (negative materials use the substantive process). The latent image is converted directly to a dye image. This dye image is complementary in colour to the original object. When this image is printed, the process is repeated in the colour paper material so that it finally appears as the correct colour in the print.

The dyes used to form the image in the negative are chosen to give the best results in the printing stage, rather than to be suited to visual requirements as in transparency materials. It is therefore possible to use integral masks in the film. These masks are designed to reduce the adverse effects of the unwanted absorption of the dyes. For example, the blue absorption of the magenta dyes, and the green absorption of the cyan dyes are often very objectionable, and suitable masking techniques are used to overcome these faults. Such masks give rise to the typical orange appearance of colour negatives. The dyes used to form the print image are similar to those used in transparency materials as they must be matched to visual requirements. Similarly the spectral sensitivities of negative and print materials

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

NEGATIVE COLOUR FILM PROCESSING. 1. Subject consisting of blue B, green G, red R, white W, and black B. 2. Exposure produces latent images in the layers sensitive to the colours. 3. Colour development produces a negative silver image together with negative dye images in each layer. 4. The silver is removed by bleaching and fixing, leaving only the dye images. These are negative; areas corresponding to blue in the original are yellow, green becomes magenta and red becomes cyan.

need not be the same as for transparency materials. In particular the print material has sensitivities designed to match the printing process, and as in black-and-white photography the print material sensitivity may differ considerably from that of the negative material.

Generally negative materials have a low contrast and are used with printing papers of high contrast to give an effective contrast similar to transparency materials. The advantage of a low contrast negative is that it has a reasonable latitude for exposure, and any discrepancies in exposure can be largely compensated during the printing stage. With transparency materials there is no possibility of compensating for over or under-exposure so their effective latitude is small. A further advantage of negatives is that they need not be exposed only in one type of lighting. Again the effects of exposing in, say, daylight and tungsten light can be compensated in printing so that the final print in either case is reasonably well balanced. P.W.

DYE DESTRUCTION AND DIFFUSION SYSTEMS

While the majority of colour materials are based on the chemical formation of a dye image during processing, it is equally possible to conceive the reverse system. In other words, we can start with three dye layers—cyan, magenta and yellow—and remove the dye in some way in accordance with the photographic image formed in each layer.

Two types of processes use this idea: dye destruction and dye diffusion. Both are used for subtractive colour photography; the principles of the formation of the coloured image are therefore the same, though the chemistry and certain practical aspects are significantly different.

Dye Destruction. When three differentially sensitized layers of an integral tripack film each contain a final dye, the image-forming relationships are reversed as compared with a dye-forming system. The chemical process of dye destruction involves a reaction between the dye and the by-products of development of the first (negative) silver image—or alternatively a reaction between that silver image and a subsequent processing bath (e.g. bleacher). In either case the dye is removed where the silver image is formed. The remaining dye—assuming a negative silver image—thus corresponds to a positive image. So a dye destruction system yields a reversal positive picture in one stage, without reversal processing. The complete processing procedure therefore consists only of development of the silver image and its removal (and removal of the unused silver salts).

The latent images in the three sensitive layers control the removal of dye, though indirectly. As the dyes in the layers also act as their own filters, no separate filter layer is necessary. Thus

DYE DESTRUCTION PROCESS. 1. Subject (or transparency) consisting of blue B, green G, red R, white W and black B. 2. On exposure and development silver images are formed in the appropriate layers of the material, the latter already containing complementary dyes in the same layers. 3. Dye bleaching removes the dye in the image areas corresponding to the silver image. 4. Removal of the silver leaves only a positive dye image.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

if the top, blue sensitive emulsion already contains a yellow dye, this automatically holds back blue light from the lower two layers. Magenta dye in the second layer holds back green light from the bottom, red sensitive emulsion. The speed balance of the three layers must, however, be different, to allow for the light lost by absorption through the dyes. In effect the bottom layer must thus be more sensitive—even to red—since the yellow and magenta dyes absorb not only blue and green light, but also some red.

Image patches corresponding to the same four colours as considered before—white, green, magenta and black—are reproduced in much the same way as with a reversal dye coupling film. Thus for the white patch all layers are exposed and during processing all dye is therefore destroyed. With no dye in the transparency, all the light during projection is transmitted on to the screen to yield a white patch. A green patch develops a negative image in the magenta dye layer, destroying the magenta dye. The yellow and cyan dyes from the other two layers are left and combine to form green. A magenta patch similarly destroys the cyan and yellow dyes in the red and blue sensitive layers, leaving only magenta in the green sensitive layer. Finally a black patch produces no image in any of the layers so that all three dyes remain intact and absorb all the light during projection.

Dye Characteristics. The colours used in dye destruction processes are still imperfect in their absorption characteristics—in other words their transmission is still not ideal. The dye deficiencies however are generally less pronounced (lower unwanted absorptions) than with dyes formed in the emulsions. This is because the choice of dyestuffs available for dye-destruction systems is considerably wider; the film manufacturer is not confined to a compromise of chemical and colourimetric dye properties. Dye destruction processes therefore can offer at least potentially better colour reproduction though the limitations of emulsion sensitivity (and their overlaps) are still present.

A second aspect of such a system is that more light-fast dyes are available for it. The comparatively restricted range of dyestuffs that can be formed as byproducts of a dye-coupling process in development is almost invariably light-sensitive to some degree; the dyes of such colour images therefore tend to fade when exposed to strong light for long periods. The dyes used in dye destruction systems are produced by different chemical processes and belong among the most stable dyestuffs as far as their sensitivity to light is concerned.

Neither of their factors guarantees perfect colour reproduction with a dye destruction process, since the sensitometry of the material is still dependent on the balance and other properties of the three individual emulsions. If the characteristic curves for the three emulsions do not coincide, or diverge over part of their range, the material will still exhibit colour casts and colour variations at different exposure levels.

Negative Dye Destruction. While a straightforward dye destruction system would be suitable for a colour transparency film, materials of this type actually available are almost exclusively intended for making colour prints. This is because the inclusion of a dye in each emulsion layer, complementary to the sensitivity of that layer, greatly reduces the effective speed. So it is not practical to produce a dye-destruction film which is sufficiently fast for a camera material.

While the system just described would produce positive prints (or transparencies) from a positive colour transparency, the process can equally be modified for negative-positive working. In contrast to a dye-forming system,

TRANSFER DIFFUSION SYSTEM. 1. Original subject consisting of blue B, green G, red R, white W, and black B. 2. On exposure, latent images are formed in the negative film layers according to their sensitivities. Adjacent layers contain dye coupled to developer. 3. At the beginning of development the dye-developer molecules from the layers diffuse into the adjacent emulsion layers to develop the silver images there and at the same time anchor the dye in place. 4. Towards the end of development the dye-developer molecules not used up in developing the negative silver image diffuse into the positive of contact with the negative, and there reconstitute the colours in the original. The whole process takes about a minute.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

this becomes more complex and in fact corresponds to reversal processing. The procedure starts with ordinary reversal processing, to yield a negative silver image—via a positive one—from the colour negative. It thus involves the usual stages of first development, bleaching of a silver image, re-exposure and second development. The negative silver image is then bleached together with the dye in those image portions, leaving a positive dye image. This then is a positive of the negative dye image in the colour negative.

Dye destruction materials of this kind are again available only for making colour prints and are subject to the same problems as well as means of control as dye-forming negative-positive colour print systems.

Dye Diffusion. A further system of colour photography, which has more in common with dye-destruction than dye formation, is dye diffusion. This is at the same time the colour counterpart to diffusion transfer. It is used in a camera material, but yields positive colour prints and does so within a minute or two of exposure.

Dye diffusion processes are based on a tripack colour film of the usual differentially sensitized blue, green and red-responsive emulsions. Associated with each emulsion is a complementary dye layer containing the dyes chemically linked to a developing agent. These dye-developer molecules are free to diffuse out of their layers once the latter are permeated by an alkaline activating solution.

During exposure each sensitive layer records its corresponding component of the subject colours, forming a latent negative image. During processing, the dye developer molecules develop the image in the corresponding layers; the *unused* dye-developer (where no negative image was formed in each layer) diffuses out of the negative into the receiving layer of a positive material. The latter is in contact with the negative film during processing. The positive receiving layer thus builds up a positive dye image, complementary in tone values to the negative developed in the three film layers. This dye positive is then the final picture.

Like an integral tripack reversal colour film, the dye diffusion process provides virtually no latitude either of exposure or of colour adjustment. It thus has all the drawbacks of a reversal material, as well as the limited tone range of a print material. On the other hand it has the immense advantage of providing a finished colour picture almost instantaneously. L.A.M.

COLOUR FILM PROCESSING

Processing procedures for colour films depend primarily on whether the material is a negative film for producing a colour negative in complementary colours or a reversal film for producing a positive colour transparency. Most of the processes, negative and reversal, are currently of the subtractive tripack type employing three selectively sensitized layers which are developed into colour images by means of chromogenic developers. Additive reversal materials are processed by similar stages to subtractive films, but black-and-white developers are used to form a black silver image in a single layer.

Some manufacturers have marketed processing kits containing all the chemicals required for user processing of the material, and in a few cases have released formulae. Suitable formulae have also been published independently.

SUBTRACTIVE NEGATIVE COLOUR FILM

The processing procedure for modern multilayer negative colour film is comparatively simple and hardly more complicated than for making black-and-white negatives. The processing of these colour films can be carried out with much the same equipment, apart from a few minor modifications and some additional items. The maker's instructions should be closely followed for each material, since different films of similar structure may react differently in processing.

Principle of Processing. The steps of producing a colour negative are:

(1) Colour development produces in each layer a dye image and a silver image, the amount of dye generated being proportional to the silver developed.

(2) An intermediate step stops development and removes developer and by-products. This can be done simply by prolonged washing but, in general, it is advisable to use a stop-bath. This solution not only interrupts the development process in a safer and more controllable way than washing, but, at the same time, facilitates the removal of certain unwanted by-products. In some processes a combined stop-fix bath is used with a hardening agent.

(3) Wash for at least 5 minutes.

(4) The next operation removes the unwanted silver image (and the unchanged silver halide if no fixing agent has been used in the stop-bath). There are various ways of carrying out this process. The traditional method is to use a potassium ferricyanide bleach bath followed by a fixing bath. This method has been largely superseded by the use of combined

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

bleach-fix solutions in which the ferricyanide is replaced by organic iron compounds. Bleach-fix solutions of this type have good keeping properties and less tendency to stain.

(5) The processing is finished as usual by thorough washing, in some cases preceded by a hardening bath.

Colour Development. The developing agents used universally now are salts of diethyl-para-phenylene diamine, or its derivatives. The salts may be the hydrochloride, the sulphate or the sulphite. In addition to one or other of these agents, the colour developer contains a large amount of sodium carbonate and a small quantity of sodium sulphite to improve its keeping properties by protecting it from aerial oxidation. A further ingredient is potassium bromide, while hydroxylamine hydrochloride may be included as an anti-stain agent.

The composition of the colour developer varies according to recommendations of different makers, since the characteristics of the colour materials themselves vary appreciably. Attempts have, however, been made to compound a colour developer universally suitable for an appreciable number of negative colour films. A formula suggested by H. Gordon is:

Para-diethylamino-aniline hydrochloride or sulphate (diethyl-para-phenylene diamine hydrochloride or sulphate)	52 grains	3 grams
or		
Para-hydroxyethyl-ethyl-amino aniline sulphate (hydroxyethyl-ethyl-para-phenylene diamine sulphate)	70 grains	4 grams
Disodium salt of ethylene diamine tetra-acetic acid	26 grains	1·5 grams
Potassium carbonate	3 ounces	75 grams
Sodium sulphite (anhyd.)	35 grains	2 grams
Potassium bromide	44 grains	2·5 grams
Tripotassium phosphate	175 grains	10 grams
Water to make	40 ounces	1,000 c.cm.

The development time, depending on the make of film, is in the region of 6–12 minutes at 65°F.

Stop Bath. As in black-and-white processing the stop bath is weakly acid but its pH value must be more carefully adjusted and controlled. The acid is usually acetic acid buffered with sodium acetate (which may be produced in the solution) to obtain and maintain the pH value in the best range between pH 5·0 and 6·0. A typical formula is:

Acetic acid (glacial)	420 minims	22 c.cm.
Sodium hydroxide	160 grains	9 grams
Sodium sulphite (anhyd.)	9 grains	0·5 grams
Water to make	40 ounces	1,000 c.cm.

In some cases an addition of fixing and hardening agents is recommended. A suitable stop-fixer is:

Sodium sulphite (anhyd.)	175 grains	10 grams
Sodium thiosulphate (cryst.)	8 ounces	200 grams
Ammonium chloride	350 grains	20 grams
Sodium bisulphite	265 grains	15 grams
Water ot make	40 ounce	1,000 c.cm.

For a hardening stop-fixer the sodium bisulphite might be replaced by 88 grains (5 grams) citric acid and 175 grains (10 grams) potassium alum.

The time of treatment in the stop bath is normally 5 minutes, followed by a wash of about 10 minutes in running water.

Bleach Bath. When potassium ferricyanide is used, it can either be applied as a plain solution, containing 7 per cent potassium ferricyanide and 2 per cent potassium bromide, or with the addition of pH controlling agents, such as mono- and dibasic sodium or potassium phosphates.

Bleaching normally takes 5 minutes and is followed by rinsing for 5 minutes and fixing with sodium thiosulphate. The fixing bath can be either a plain 20 per cent solution of sodium thiosulphate or hardening and pH controlling agents (alum and sodium acetate respectively) may be added.

Combined bleach-fix solutions simplify the process, but they cannot be prepared by simply mixing sodium thiosulphate with ferricyanide. This mixture, the well-known Farmer's reducer, has only very limited keeping properties.

One method of making up a bleach-fix solution is based on the use of ferric compounds in combination with a sequestering agent like ethylene-diamine-tetra-acetic acid. A formula for a bleach-fix solution of universal application, published by H. Gordon, is:

Potassium bromide	1½ ounces	30 grams
Sodium thiosulphate (cryst.)	8 ounces	200 grams
Ferric salt of ethylene-diamine tetra-acetic acid	2½ ounces	60 grams
Sodium carbonate (anhyd.)	88 grains	5 grams
Potassium thiocyanate	175 grains	10 grams
Water to make	40 ounces	1,000 c.cm.

The average time of treatment is 10 minutes. A thorough wash follows the bleach-fix process or the bleach formula based on potassium ferricyanide. These solutions can be used for negatives as well as prints. When no hardening agents have been used in the processing solutions, it may be advisable to apply a hardening solution containing 2 per cent formalin and 3 per cent sodium carbonate (anhyd.) for about 5 minutes, followed by a short wash. This solution also stabilizes the dyes.

Processing Equipment. When negative colour film is used on a fairly small scale, very little more equipment is needed than for black-and-white film. For negative processing, spiral tanks or cut-film tanks can be used, but if the processing is to be carried out on a large scale, deep tanks are essential. These should be similar to the normal type used for D. & P. work, although not all tanks of this type are suitable.

The developer tank has to be enclosed in a water jacket so that the development temperature can be thermostatically controlled. For this reason the developer tank should be a good conductor of heat, and a stainless steel tank is therefore advisable.

CC-0. Kangri Gurukul Digital Preservation Foundation, Chandigarh

However, the bleaching solutions attack stainless steel and a plastic or stoneware tank must be used for this stage of the process; copper tanks may also be used with ferricyanide bleaches.

On a large scale, continuous processing is both more economical and reliable. In that case, stainless steel or hard rubber tanks are normally employed (as in black-and-white work) except for the ferricyanide bleach. The temperature is generally controlled by heat exchangers at the recirculation stage, where the solutions are pumped round from a reservoir through the tanks. Replenisher solution is added at this stage to keep the composition of the solutions constant, some of the old solution being thrown away if necessary. This replenishment must be accurately controlled by routine analysis of samples at fixed time intervals and the whole process checked by sensitometric strips being included at regular intervals.

SUBTRACTIVE REVERSAL COLOUR FILM

Reversal colour materials are of two main types—those which have the colour-forming elements, couplers, actually incorporated in the emulsion layer and those in which the couplers are added to the developers.

Non-incorporated Couplers. The processing of this type of material is complicated and only undertaken on a large scale on continuous machines, with rigorous analytical control of the solutions. These materials are integral tripacks with separate red, green and blue sensitive layers (from base to surface) and the essential steps in the processing are:

(1) Development of the latent image to a negative with a black-and-white developer of the type generally used for reversal work.

(2) Flashing to red light to fog the unused silver halides in the red sensitive layer.

(3) Development in a cyan-coupling developer to give silver plus a positive cyan dye image.

(4) Flashing to blue light and re-development to give silver plus a yellow dye image in the blue sensitive layer.

(5) Flashing to green light followed by magenta coupling development in the green sensitive layer.

(6) Bleaching all the silver, to leave the positive image composed of three subtractive dye images.

Many variations on this outline are possible, e.g., dye toning or mordanting processes instead of the more usual dye-coupling ones, fogging developers instead of exposure to light, etc., and, of course, washing, hardening and stop baths are also necessary. The processes are complicated, and in any case details are not published.

The materials are usually prepared in the standard and sub-standard cine sizes and are processed on continuous machines, identifying numbers being punched on the leaders before splicing them together. Still pictures taken on 35 mm. film are cut after processing and mounted in cardboard or plastic frames ready for viewing. These operations may also be done automatically.

Reversal materials of this type can also be used for making prints for viewing by reflection.

Incorporated Couplers. The materials which contain the colour forming couplers already in the emulsion layers are very much simpler to process, and on a large scale may be done on batch processing machines or in tanks in the same way as black-and-white materials. More baths are needed but the principles are just the same. Care must be taken that the tanks are of suitable material as with negative colour films.

For the amateur, the main points to watch are temperatures and times, and it is most important that the instructions given by the manufacturers are carefully followed.

Principle of Processing. Steps in the production of a reversal image on monopack colour film are the following:

(1) First development in a negative developer of the M.Q. type (or amidol) producing a negative silver image.

(2) Wash, or treatment in stop and hardening solutions.

(3) Re-exposure of the unaffected silver salts to a strong light source.

(4) Colour development. There the re-exposed silver salts are reduced to silver and dyes are simultaneously produced in the three layers.

(5) There may again follow some intermediate treatment in hardening and stop solutions.

(6) Bleaching to remove all the silver, leaving only the dyes and silver halide which is dissolved in the usual way with a hypo solution.

For large-scale work deep tanks with floating lids to cover the solutions and prevent oxidation are preferable. Normal stainless steel film clips and hangers may be used for holding the film during processing. Single rolls on 35 mm. film lengths can be processed in an ordinary developing tank; some types have transparent-ended reels to permit re-exposure without removing the film from the reel.

First Development. Certain features are common to all developers used at this stage.

Firstly, they all possess a very high activity and are used more concentrated than for normal black-and-white development. The alkali content is kept on the high side as well.

Secondly, they contain a small concentration of thiocyanate which has the property of dissolving silver halide, and therefore helps to produce transparencies with clear whites by removing any excess of silver halide.

While most of these developers are of the

M.Q. type, amidol has also been used for some makes of colour film.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The usual range of concentrations of various published formulae is:

Metol	25–50 grains	1·5– 3 grams
Sodium sulphite (anhyd.)	1– 2 ounces	25–50 grams
Hydroquinone	70–100 grains	4– 6 grams
Sodium carbonate (anhyd.)	1–1½ ounces	25–35 grams
Sodium or potassium thiocyanate	20–100 grains	1–5 grams
Potassium bromide	20–100 grains	1–5 grams
Water	40 ounces	1,000 c.cm.

The developing time ranges between 10 and 35 minutes.

The M.Q. developers require either a stop or a combined stop-hardening bath (1 per cent acetic acid with 2 per cent sodium acetate and 3 per cent chrome alum) after development, and then a short wash. Films developed in amidol do not get any treatment in stop and hardening solutions as amidol carries on development even in an acid medium. They are thoroughly washed for about 20–30 minutes.

Re-exposure. After the first development and stop bath, the remainder of the processing can be carried out in white light, as the next step is to fog all the unused silver halide grains by exposure to light. As the speed of the wet film is very low, the exposure must be quite heavy. It is not possible to over-expose it, but the exposure must be sufficient or the full density will not be obtained from the second (colour) development.

The recommended exposure is usually about 5–10 seconds each side, 1 foot from a Photoflood lamp, or its equivalent. If any quantity of processing is to be undertaken, it is best to use an exposing box with two Photofloods, the transparency being hung between them and both sides being exposed simultaneously. Sheets of glass should be placed so as to protect the lamps from accidental splashes of cold water which might crack them.

Where roll films or 35 mm. films are being processed in a tank, they must be unrolled and hung flat on clips for re-exposure. However, if the ends of the spiral reel are made of transparent plastic, the reel may be rotated under the lamp so that the light penetrates between the coils of film and reaches every part of it.

Colour Development. The composition of the colour developer is similar in principle to the colour developers used for negative film. No universal formulae have been published, as the developer must be closely matched to the film characteristics.

The time of colour development ranges between 10 and 20 minutes at 65°F.

In all cases, it is necessary to put the films through stop and hardening baths or combined solutions and they must then be washed thoroughly.

Final Steps. The removal of the silver is carried out in bleaching solutions containing potassium ferricyanide, in most cases in mixture with potassium bromide.

These bleaching solutions convert the black metallic silver produced in the first developer as well as in the colour developer into silver bromide. The latter is then fixed out in a plain 20 per cent solution of thiosulphate. A wash of about 20 minutes ends the process.

Precautions. Accurate and careful work is essential in reversal colour processes in order to obtain the best results.

It is important that the two developers should be maintained at the correct temperature within half a degree, and the other solutions should preferably be at the same temperature, although it is not essential to maintain them quite so accurately.

Equally important is the degree of agitation which must be standardized. Cut sheet films may be raised from the solution, drained and lowered back, or a spiral tank may have the spiral rotated at regular intervals, e.g., every 30 seconds.

On a larger scale, continuous circulation of the solution, bursts of compressed nitrogen, or mechanical paddles are methods in regular use for ensuring good agitation.

With the rapid growth of colour photography, the speed of processing has been increased in order to improve plant output. Short processing times have been achieved by working at higher temperatures and reducing the number of baths, e.g. by substituting "blixes" for separate bleach and fix baths—this tendency is likely to continue.

OTHER COLOUR MATERIALS

Additive Reversal Colour Film. The processing of the additive colour materials is similar to that for black-and-white reversal materials since the colour comes from the screen or reseau and not from dyes formed by colour development.

The usual sequence is:

(1) First (negative) development.
(2) Bleaching, clearing, and hardening.
(3) Re-exposure.
(4) Second (positive) development.

Additional washes are required between each bath, and the same precautions as to accurate working should be taken as in the case of the subtractive materials.

Colour Processing in the Camera. Diffusion transfer colour film is based on a different type of tripack in which the layers contain complex dye-developer molecules which can be activated to cause migration of dye to a receiving sheet, thus forming the positive image. This special processing is very rapid, being complete within a minute, since the silver and unwanted chemicals do not have to be removed but are left in the discarded negative. J.Mo.

COLOUR PRINTS. Many people look on a hand-coloured photographic print as a satisfactory substitute for one made by direct colour photography. It is certainly possible to achieve very beautiful results, much depending upon the skill of the worker and his knowledge and sense of colour.

The principal types of colour used for handwork on prints are dyes, transparent oil colours, and pastel chalks. It is also possible to use chemical methods.

Most subjects are suitable for hand-colouring, but simple colour schemes are always the best.

When colours in the original are likely to render as dark tones in the print, it is advisable to use a suitable filter to lighten the tone when taking the picture.

Transparent Colours or Dyes. Dye tinting is the simplest method of colouring prints. The colours can be bought in sets either in solution or dry, coated on sheets of paper (these must be dissolved in water for use). Dyes are transparent and can be used for prints, lantern slides, or larger transparencies. The dyes can be diluted with water and they are easily applied as an even wash of colour. Dyes of different colours can be combined to give any desired tint. Being fully transparent they do not obscure any of the detail, tone and gradation of the photographic image. If the first attempt at colouring does not give a strong enough effect, a further wash or washes of colour may be applied.

The best practice is to build up to the depth of tint required by applying successive washes of colour. If the result looks exaggerated, the colours can be toned down by soaking the print in water. Dyes cannot be completely removed from the emulsion by soaking, but stubborn colours will usually yield to a weak solution of carbonate of soda.

COLOUR CHART. This indicates what colours are required to mix a particular shade. The outer circle covers pure colours, the artist's primaries being red R, yellow Y, and blue B. The inner segments show the tones obtained by adding white. (These correspond respectively to the subtractive primaries cyan, magenta and yellow.)

OIL COLOURING. 1. Attach print to a hard surface (e.g., a board covered with blotting paper). Clean surface of print with turpentine, and leave to dry. 2. Mix colours on a palette, thinning with turpentine as necessary. 3. Apply colour to main areas with a cotton wool rubber. 4. Grade the colour to correct shade by carefully rubbing off excess with clean cotton wool. This also blends edges and hard outlines. Bottom: *Cotton wool rubber, consisting of a tuft of cotton wool wrapped round the end of an orange stick. Replace cotton wool frequently.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

PRINT COLOURING WITH DYES. 1. *Soak prints in warm water.* 2. *Mix dyes as required from concentrate or solid.* 3. *Place print on a sheet of blotting paper, and support on a glass plate.* 4. *Blot off surplus moisture.* 5. *Apply washes of diluted colour to large areas.* 6. *Take up excess liquid with edges or corners of clean blotting paper, to avoid sharp colour edges.* 7. *Use small brush to apply more concentrated colour to details.*

Good quality brushes should be used, particularly for small size prints. Size O is suitable for very small details and 2 and 4 for larger areas.

Small prints can be very effective when coloured. A semi-matt surface is probably best for taking the colour. The print to be coloured is soaked for five minutes, laid upon a sheet of glass, and the surplus moisture blotted off. The print is then ready for colouring with successive faint washes. The washes should be carried right up to the edge of the outline without overlapping on to an adjacent colour. Spaces between the edges of different colour areas are then filled in with a mixture of both colours.

The depth of the tint will depend upon the subject. In general, prints for colouring should be fairly light in tone; dark prints tend to look dull and muddy.

Portraits are best kept in a high key and may be sepia-toned first.

Oil Colouring. Prints can be coloured with oil colours, but it is a difficult job and best left to the professional artist. Transparent oil colours are used; they must not be mixed with white or opaque colour. The print, preferably on semi-matt paper (sepia-toned in the case of a portrait), is prepared by applying the special medium supplied by the maker of the colours. Artists' megilp thinned with pure turpentine may be used.

The colours are applied to areas of any size on tufts of cotton wool; brushes are used for the smaller details.

The print should be fixed by its four corners to a smooth board covered with several sheets of blotting paper.

A small tuft of cotton wool is wound around the point of a small piece of wood; these are supplied in the colouring outfits. The tip of the cotton wool is worked into a fine point. This is placed in the colour, the latter being upon a palette or sheet of clean glass. The cotton wool is then applied to the area to be coloured, working it into the surface, and following the outlines carefully. The colours may be worked further into the surface of the print with another piece of clean cotton wool. Any colour found incorrect or excessively brilliant can be reduced or removed with cotton wool moistened with the thinning medium.

After colouring is completed the print should be dried in a warm, dust-free atmosphere.

Often the reds, crimson and carmine can be made brighter by the addition of a little yellow. Yellow can also be added to the greens to produce greater brilliance.

Greys are the result of equal parts of blue, yellow and crimson diluted according to the depth of the grey.

A few experiments with the actual colours along these lines will soon indicate the possibilities.

Pastel Chalks. Coloured chalks are extensively used by professional colourists, but their use

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

calls for considerable skill: the colour is opaque and needs to be applied very lightly. The print should be light in tone and preferably of a fairly large size.

The print surface is prepared by rubbing it lightly with fine pumice powder, and the colours are then applied with small pieces of cotton wool. Or the crayon may be rubbed on a piece of cartridge paper from which it is wiped off with a piece of cotton wool and applied to the print. Excess or overlapping colour can be removed with a pointed india rubber. Fine detail can be filled in with a small piece of chamois leather twisted around a match stick. Very fine detail is best put in with water colour.

Chalk colouring needs to be fixed: the print may be held in the steam from a kettle, or sprayed with the special liquid fixative sold by the makers of the colour.

Colour Blending. All colouring should be done in soft daylight, as it is difficult to judge the effect of the colour by artificial lighting.

The successful colouring of photographs depends very largely upon an understanding of the art of colour blending.

The best results will be obtained when the colours are well diluted. Very vivid colour effects are rarely successful. For small prints the colouring should be delicate.

The beginner should study the effects of painters and especially note the relative depth of colour of near and more distant objects. The latter are much more soft in colouring than those close at hand. By this means depth can be easily conveyed.

Colours are rarely used alone. The results are most harmonious when a given colour is obtained by combinations. The following is a short guide to some of the hues that are obtained by combinations of colour.

Red and blue make purple.
Sap green and yellow make pale green.
Flesh and yellow make brick red.
Red and yellow make orange.
Navy blue and green make dark green.
Carmine and blue make purple.
Yellow and blue make green.

Still further modifications are possible as any of the colours in an above pair can be given a deeper tone suggestive of either by using more of one and less of the other. For example, more yellow and less blue will produce a light green while more blue and less yellow yields a blue green.

Chemical Methods. Various methods have been used which utilize chemical means of hand-colouring. These processes are usually more complicated than normal hand-colouring.

One such system that has been employed uses normal chemical toning baths and a hand-painted resist to prevent parts of the photograph from being toned. In this way, only selected parts of the image are toned in one colour. The process is then repeated with fresh resists and other colour baths, building each colour up separately.

With another process, special materials are employed and the colour is applied selectively with a brush, any mixture of colours being possible. The colours react with the silver image in the print, replacing it entirely in proportion to the silver present. In this way, a pure colour image is obtained. R.M.F.

Book: *The Complete Art of Printing and Enlarging*, by O. R. Croy (London).

COLOUR LIGHTING. The lighting needed for taking colour photographs must fulfil certain requirements.

For normal results it must be of the correct colour temperature for the colour materials being used in the camera; it must be sufficiently bright to permit a reasonably short exposure time; it must be arranged so that the brightness range of the subject is kept to a minimum; it must emit a continuous spectrum to reproduce colours accurately.

COLOUR MATERIALS

Materials for direct colour photography are generally classified according to the system of colour synthesis and type of processing employed. They fall into the following groups:

(1) Subtractive reversal materials.
(2) Subtractive negative materials.
(3) Subtractive positive materials.
(4) Additive materials.

In addition, black-and-white materials are used in various indirect processes.

Subtractive Reversal Materials. Subtractive colour materials consist of three differentially colour sensitive layers coated on top of each other as an integral tripack. These three layers are sensitive to the three primary colours: the top layer to blue, the middle layer to green, and the bottom layer to red. Generally a yellow filter layer between the top and the middle layers prevents any blue light from affecting the lower two emulsions.

The material is processed by reversal, the second development taking place in a colour developer which produces not only a silver image but also a dyed image in each layer. This dyed image is generally chosen to be complementary to the sensitivity of the layer in which it

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

is formed. Thus the blue sensitive layer yields a yellow positive dye image, the green sensitive layer yields a positive magenta dye image, and the red sensitive layer yields a positive cyan (blue-green) dye image. The three silver images are eventually removed by chemical means, and the dye images form the composite colour picture by subtractive synthesis.

There are two main types of reversal subtractive materials, requiring distinctly different processing technique.

The original materials of this kind utilize controlled individual colour development of each layer. The colour developer in each case contains the appropriate colour forming agent.

The other type of subtractive reversal film incorporates colour couplers in each layer, so that one colour developer simultaneously develops each layer to its correct colour.

Subtractive reversal film yields positive colour transparencies on the same support which was exposed in the camera. Duplicates or prints can, however, be made by printing the transparency on to a similar reversal subtractive material.

Subtractive Negative Materials. In principle these are similar to subtractive reversal materials, but are processed to a colour negative only. The resultant image is not only reversed tonally, but also appears in colours complementary to those of the original subject. For instance blue skies are recorded brownish-yellow, greens as magenta, yellow as blue, etc.

The choice of colours with negative films is fixed by convention rather than by scientific necessity; the purpose of the colours is to enable the three layers to cover the visible spectrum in three approximately even ranges.

These negatives can be printed by contact or enlargement to produce colour prints, black-and-white prints, or colour transparencies. In each case the colour negative can be used to produce unlimited numbers of positives.

In addition, the colour negatives may be used to produce direct separation positives for various indirect colour printing processes.

Some subtractive negative materials incorporate suitable masking layers to compensate for the shortcomings of the image dyes. The absorption of these dyes often deviates appreciably from the ideal absorption required for perfect colour reproduction. In some materials of this type the colour couplers incorporated in the emulsions are themselves coloured and thus automatically modify the response of the respective emulsion layers.

Subtractive Positive Materials. In structure and general principle subtractive positive materials are similar to subtractive negative materials. They are used for printing colour negatives to yield prints or transparencies. The positive material differs from the corresponding negative material mainly in its gradation and spectral sensitivity curves. It is available on a paper or film base.

Grain and Resolving Power. Most colour emulsions are inferior in resolving power to average black-and-white emulsion. The fact that there are at least three, and often as many as five, separate layers may lead to a certain loss in sharpness. With some materials this is accentuated by a slight degree of diffusion of the colour couplers, both within each emulsion layer and from one layer to another.

Subtractive colour films are often claimed to be grainless. While the grain size in each emulsion is probably no smaller than it would be with an average black-and-white material, the graininess itself tends to get lost. This is partly because the image dyes do not form as distinct grains as the silver image, partly because the differently coloured dye grains (such as they are) are very rarely in register in the three layers, and partly because the contrast of each dye image is lower than of a corresponding black-and-white silver image.

In practice, lack of sharpness in colour images is sometimes due to inadequate colour correction of the lens used to take the picture.

Colour Balance. As all colour materials rely on individual sensitivity to the three primary colours, they will yield correct colour reproduction only if the light contains these three primaries in a specified proportion. In practice therefore colour materials are balanced for light sources of given colour temperatures by adjusting the relative emulsion sensitivities.

Reversal films are generally available as daylight type and artificial light type materials. Daylight film is balanced for average daylight (5,500 to 6,000° K) and artificial light film may be balanced either to 3,200° K (commercial studio illumination) or 3,400° K (photofloods).

If the colour emulsion is exposed by light of a different colour temperature than that for which it is balanced, the colours will be falsified. Thus a daylight type film exposed by Photoflood light will show very warm (reddish) colours, while an artificial light type film exposed by daylight will give pictures with a bluish hue. With reversal materials it is thus specially important to match the light source to the colour balance of the material, as no effective correction can be made after exposure.

Most colour materials can, however, be used with light sources for which they are not balanced, if a suitable colour correcting or colour compensating filter is fitted in front of the camera lens.

With subtractive negative film the printing stage offers an opportunity for correcting the colour balance. For that reason the matching of the film to the light source is not so important, and there are many negative colour materials which can be used equally well by daylight or by artificial light, provided light sources of different colour temperatures are not mixed.

Speed. At one time colour materials used to be comparatively slow; current emulsions do,

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

however, reach the sensitivity of high-speed black-and-white films.

The standard method of determining the speed of reversal colour films necessarily differs from that for black-and-white materials; speeds themselves are however expressed in the same notation and when used with exposure meters or tables yield correct results. There is no standard for determining the speed of colour negative film. Figures given by manufacturers are therefore equivalent speeds and mean that the material should be exposed like a black-and-white film rated at the quoted speed.

Gradation. Most colour materials, especially reversal ones for transparencies, cover a comparatively short scale of tones. This is partly due to the fact that the maximum density obtainable with the dyes is less than with silver, and partly to the fact that the emulsion is designed to be contrasty to yield good colour saturation. Some makes provide an alternative emulsion of even greater contrast for special purposes such as photomicrography and copying in colour.

One result of the comparatively contrasty gradation of the film is a very limited exposure latitude. This is in part due to the limitations imposed by the reversal process and to the extreme thinness (and low coating weight of silver) of the emulsions. The exposure latitude is further reduced by the fact that it is difficult to match the gradation of the component emulsions of a tripack material sufficiently accurately over the whole range of tones. So incorrect exposure results not only in loss of tone at the highlight or shadow end of the scale, but also upsets the colour balance.

Subtractive negative materials usually have a softer gradation and thus an increased exposure latitude. They are, however, still limited by the lack of colour balance when the exposure deviates appreciably from its optimum value.

Special soft-gradation negative and positive materials are made for duplication from colour transparencies. The negative film, also known as inter-negative, produces a low-contrast intermediate negative from the transparency, without excessive colour distortion at the ends of the tone scale. The inter-negative is then printed on positive colour film or paper to give duplicate transparencies or colour prints.

Duplicating reversal film is a subtractive reversal material that yields low contrast direct transparencies. It is used for photography when large numbers of duplicate transparencies are likely to be required, and also serves as the master print for duplicating motion picture films by reversal. Making the original transparency on duplicating reversal material avoids excessive contrasts which would be further enhanced by the reversal printing process.

Image density. As colour films build up the image by layers of dye, the maximum density obtainable is usually rather lower than with a silver image. This is of particular significance in colour motion pictures, where the film may also have to carry a contrasty black-and-white sound track.

Positive colour materials have images containing appreciably less dye than transparency films or negatives. Since however the light has to pass through the dyes twice (to reach the white paper backing and again on reflection from the paper), the effective reflection density is of a similar order as with transparency materials.

TYPES OF COLOUR MATERIAL

Type	*Speed (ASA)* D.	A.	*Available as*	*Characteristics and Uses*
Subtractive negative	25-100	25-100	S, R, M	General photography; processed by maker, trade or user
Subtractive reversal I	10-64	16-40	S, R, M	General photography; emulsion incorporates no couplers; processed by maker only
Subtractive reversal II	25-64	25-64	S, R, M	General photography. Emulsion incorporates couplers; processed by trade or user
High speed subtractive reversal	100-200	80-200	S, R, M	Photography by poor light. Emulsion incorporates couplers. Processed by trade or user. Forced processing for extra speed often possible.
Positive print	—	—	Pp	Making paper prints from colour negatives
Positive transparency	—	—	S, M	Making positive transparencies from colour negatives
Reversal print	—	—	Pl, Pp	Making direct prints from colour transparencies
Duplicating reversal	—	—	S, M	Making duplicate transparencies from colour transparencies
Internegative	—	—	S, M	Negatives from transparencies for duplication

Abbreviations. D = speed of daylight type material to daylight; A = speed of artificial light type material to appropriate artificial light source. Availability: S = sheet film; R = roll film; M = 35 mm. miniature film; Pl = plastic opaque base; Pp = paper.

Supports. Most colour materials are coated on cellulose acetate safety film base. Subtractive reversal materials for print-making from transparencies are often coated on a white opaque plastic base.

Positive print materials for making prints from colour negatives may be coated either on a white plastic support or on paper.

Sizes. Subtractive colour materials (reversal and negative) are available in most roll film and sheet film sizes, and also as 35 mm. and 8–16 mm. cine film. The range offered by any one make is, however, usually limited; thus one brand may cover 35 mm. miniature and

narrow-gauge cine film only, while another may be available exclusively in 35 mm. film sizes.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Subtractive reversal and positive printing materials are available in roughly the same range of sizes as black-and-white bromide papers.

Keeping Qualities. Subtractive colour materials do not keep as well as black-and-white materials. Apart from normal factors of deterioration such as loss of speed, increase of contrast, etc., a complicating factor is the presence of three emulsions instead of one. Owing to their different sensitization, they may deteriorate at different rates, thus upsetting the colour balance. This is especially apparent with subtractive reversal films, where there is no way of compensating for inaccuracies in colour balance after the original exposure.

With many materials the colour balance shifts towards red with increasing age. For that reason some manufacturers have slightly overbalanced the sensitivity of their material to blue, on the assumption that the material would not be used until some months later when the colour balance should be about correct.

The ideal storage conditions for colour materials are on the whole similar to those for black-and-white materials. They should be kept in a cool dry place, and well away from fumes. After exposure the material should be processed as soon as possible.

Special Subtractive Colour Materials. Certain subtractive colour materials depart from the principles already described either to yield a colour material for special purposes or by using a different kind of process. Examples of the first kind are false-sensitized masking films, and of the second kind dye-destruction and transfer-diffusion colour prints.

A false sensitized film has a deliberately abnormal and non-complementary relationship between the sensitivities of the emulsion layers and the colours produced in them. The most usual purpose of such films is the production of colour masks when making separation negatives or duplicate colour prints from coloured transparencies. False-sensitified colour films are sometimes also used in certain fields of scientific photography to separate for instance radiation intensities as colour effects rather than to show actual colour values.

Dye destruction colour materials contain the final dyes in the three emulsion layers. During processing these dyes are destroyed image-wise. A dye destruction colour paper therefore yields a direct positive from a positive transparency, and requires reversal processing to yield a positive print from a colour negative.

In transfer diffusion colour material the dyes are also contained in, or associated with, three differentially sensitized emulsion layers. During processing of the exposed negative film, a corresponding positive dye image is transferred to a receiving layer; the latter forms the positive colour print.

Additive Materials. These are nowadays obsolete, having been displaced by subtractive materials. The latter offer overwhelming practical advantages over the additive processes.

Essentially an additive colour film consists of a panchromatic silver halide emulsion coated on top of a mosaic of transparent red, green and blue elements. This mosaic breaks up the light into its primary components and so produces small image units corresponding to the colour of the image at each point. These image units in combination with the colour units then yield the additive colour picture, which may be either negative or positive (by reversal processing).

The colour elements, usually in the form of a mechanically ruled pattern, act as filters and the emulsion has to be exposed through this mosaic. Alternatively, the colour mosaic can be a separate screen with a normal panchromatic plate exposed in contact with it. After processing the plate is bound up in register again with the same screen.

The limitations of additive materials, which were largely responsible for their disappearance, were low resolution (owing to the finite size of the screen elements), disturbing visibility of the mosaic in enlargements, and high image density since the image is formed by both silver and filter elements. Even with powerful projectors additive transparencies therefore tended to yield dim screen images. L.A.M.

COLOUR MEASUREMENT

Colour is a mental quality. It is the result of a chain of processes both physical and psychological. Radiant energy from a light source is modified by reflection from or transmission through various objects, enters the eye and is perceived, and then interpreted as a colour by the observer. The emission of energy from the source and its modification by objects are physical processes. The act of perception, involving the sensitivity of the eye, is a psychophysical process. Measurements of these processes are objective measurements. The interpretation of these by the observer is a psychological process. Classifications of colours by this process are subjective measurements.

The following is a brief survey of the psychological aspects of vision, covering colour perception and subjective colour measurements, and of the physical aspects of colour, covering objective measurements.

Digitized by Punjab Digital Presevation Foundation, Chandigarh

The process of vision is so complex that we cannot immediately specify the exact colour of an object. Red, green and blue are obviously different colours but to try to specify precisely "which red" or "which blue" of the possible reds or blues is extremely difficult.

The colour we see depends on many factors. The object may be a surface which is either glossy or matt. It may be a translucent medium such as glass, jelly or the sky. It may be large or small, round or square. Such physical attributes can affect the perceived colour of the object. The surrounding objects may be strongly coloured, black or white. The illumination may be daylight, tungsten light or sodium light. The perceived colour will be different under all these different viewing conditions.

The observer himself is equally important. A colour blind person, by definition, does not see colours the same as does a "normal" person. Even two people with so-called normal colour vision are unlikely to see colours exactly the same. And even confining observations to just one person still admits of considerable variation. The eye is not only capable of adapting itself at least partially to the illuminant, it also changes in sensitivity to colour as the illumination level changes (notably at low illumination levels, such as moonlight) and at different points on the retina (the region outside the fovea is largely colour blind).

Yet another complication is the effect of after-images. If an observer stares first at a red patch and then at a "white" surface he will see the surface as blue-green. Such after-images occur to some extent whenever the observer looks from one coloured patch to another even slightly different patch.

With such a welter of information the task of sorting it into some logical system of measurement of colour seems at first sight doomed to failure. However steps can be taken to eliminate some of the disturbing factors mentioned above. The physical attributes of patches of colours to be matched can be fixed so that a constant size and shape are used, and measurements confined to a specific type of surface or medium. The viewing conditions can be rigidly defined by using a constant surround to the patches and using a specific illuminant. The differences in observers may also be allowed for by averaging the results of many observers. Such limitations imposed on measurements must always be borne in mind when using them. It may not be valid to change the conditions for a particular system of measurement, and comparisons between one system and another must be made with caution.

Dimensions of Colour. To the layman colour has as many dimensions as there are colours. To him orange and brown are unrelated, a red rose is somehow different from a red car.

The layman seldom attempts to abstract "colour" from the complex sensations involved in looking at objects. He does not for example analyse orange and brown and conclude that they are similar in hue and different in "lightness" (Brown may be thought of as a "dark orange"). When he does consider colour itself he uses terms such as bright green; light blue, deep purple, pale yellow, vivid red—terms which are sufficient for his purpose, but are not systematic or precise enough to be useful as measures of colour.

Colour can in fact be shown to have only three dimensions. The colours mentioned above, bright green, light blue and so on can be expressed in terms of three variables, namely: hue; luminosity and saturation.

Hue is the attribute of colour which is denoted by red, orange, yellow, green, blue, violet (i.e. the hues of the spectrum) and purple (the non-spectral hue between red and violet) and, of course, all their intermediates.

Luminosity is the attribute which denotes the amount of light which an area appears to emit. The terms lightness and brightness are also used for this attribute. (Strictly, lightness refers to diffusely reflected or transmitted light but is commonly used to refer to colours from reflected light. Brightness is still frequently used, particularly when referring to sources of light, but the term luminosity is preferable).

Saturation is the attribute which denotes the proportion of chromatic colour present. Alternatively chroma may be used for the third dimension. This denotes the amount, rather than the proportion, of chromatic colour present, irrespective of the amount of achromatic colour.

For example we may have two articles which are both green. Neither one can be classed as more blue or more yellow than the other (same hue); neither can be called lighter or darker than the other (same luminosity), but one is simply a stronger green, or "greener", than the other. They differ only in the strength of greenness, that is they differ in saturation. A colour that has zero saturation (and therefore no specific hue) is termed achromatic. These colours are black, greys and white. Other colours are termed chromatic.

Any given colour is essentially some particular combination of attributes, for instance, the colour which is typically evoked by the light from a tungsten lamp is yellow in hue, weak in saturation and high in luminosity. Similarly, a ripe tomato in the sunshine is likely to yield a slightly yellowish red hue, strong saturation and moderate luminosity. Lightning in a dark sky may elicit no hue or saturation but very high luminosity, that is, an achromatic colour. The thousands of different combinations of hue, saturation and luminosity which can occur account directly for corresponding thousands of distinguishably different colours.

Luminosity and saturation are commonly confused. A "light" blue for example implies

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

not only high luminosity but also low saturation. A "bright" red implies high saturation as well as fairly high luminosity. This confusion arises because common terminology is related to common experience. A high luminosity blue in nature is also of low saturation. Highly saturated, high luminosity blues are nearly always "artificial" colours, produced by dyes and pigments. Similarly highly saturated, low luminosity, reds are uncommon.

Modes of Appearance. Basic descriptions of colours (in terms of hue, saturation, and luminosity) may be supplemented by reference to five principal types of stimulus situation which give rise to colours and to which they seem to belong. These modes of appearance of colour include the illuminant mode in which the colour is perceived as belonging to a source of light—e.g., the sun; the illumination mode in which colour is perceived in space—e.g., lamplight in the atmosphere; the surface mode with colour belonging to surfaces—e.g. colour prints; the volume mode—e.g., a clear mass of red jelly; and the film mode in which the colour seems soft and without definite location in depth—e.g., overcast sky.

The film mode is the simplest or basic mode in the sense that all other modes can be reduced to it by appropriate viewing through a small aperture in a screen. When a surface colour, for instance, is reduced to film colour, as by looking through an aperture screen, the surface mode is destroyed and the colour thereby becomes disassociated or unrelated. The several modes of appearance are classified as object modes (surface, volume, and illuminant) and non-object modes (illumination and film) according to whether or not they are related to particular physical objects.

COLOUR SYSTEMS

The attributes of hue, luminosity and saturation or chroma form the co-ordinates of a subjective colour system. The nearest approach to this system in practice is the Munsell colour atlas. In this the dimensions are Munsell hue, value and chroma. These co-ordinates are similar but not identical to hue, luminosity and chroma respectively. For objective measurements the C.I.E. (Commission Internationale de l'Eclairage—sometimes referred to as the I.C.I.—International Commission on Illumination) system is used frequently. In this the dimensions of dominant wavelength, luminance, and purity may be used.

FUNDAMENTAL COLOUR SYSTEM. The colours occupy a system of cylindrical co-ordinates: A, brightness, increasing vertically; B, saturation or chroma, increasing radially from the centre; C, hue, varying with angle about central axis.

Each system has its own specific set of dimensions. Because these dimensions are in many ways similar there is a great temptation to confuse them. Hue and dominant wavelength, purity and saturation for example are often referred to as though they were simply alternative names for the same thing. This is not so. It is like saying that Magnetic North and Geographic North are the same. Each is useful for a particular purpose; it is possible to convert measurements from one system to another but they are not interchangeable at random.

Subjective Colour Systems. The most convenient way of representing a subjective colour system is in the form of a solid with cylindrical co-ordinates; with luminosity increasing vertically, saturation increasing radially, and hue varying with the angle about the luminosity axis. As an analogy we may think of lines of latitude representing luminosity, lines of longitude representing hue and the horizontal distance from the axis representing saturation.

The Munsell system of colour presents the nearest approach to this colour solid in practice. In this system the colour samples are presented in the form of about 1,000 coloured paper chips. These are suitably arrayed with respect to the dimensions of Munsell hue, value and chroma. The perceptual spacing of the colour samples is approximately uniform throughout the system.

Any principal vertical section through the Munsell system reveals varying values and chromas of two opposite constant hue planes—e.g., yellow and purple-blue—separated by the neutral (achromatic) axis. Any horizontal section, on the other hand, shows a plane of constant value with varying hue and chroma. The hue, value, and chroma scales are naturally used for describing or notating the standard colour samples. The Munsell notation Y 8/12 for instance, refers to a sample of yellow Munsell hue, value 8, and chroma 12. This particular sample normally evokes a colour of yellow hue, rather high lightness and strong chroma.

Any unknown colour sample can be identified or specified simply by matching it in daylight with a notated colour sample, if such is available; moreover, interpolation is feasible within the orderly standard arrangements of Munsell samples.

Objective Colour Measurements. If we knew enough about the process of vision we could, for simple situations, calculate the actual

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

SUBJECTIVE COLOUR SOLID. This type of subjective colour system is based on cylindrical co-ordinates; luminosity (L) increases vertically, saturation (S) increases radially, and hue (H) varies with the angle about the central luminosity axis. The Munsell colour solid is of this basic type.

appearance of a colour once we knew the physical properties of the light entering the eye. As yet this cannot be done, but it is possible to calculate whether or not two lights look alike to a person with average colour vision. If they differ we cannot say what the difference will look like although we can obtain some idea of the magnitude of the difference.

Such objective measurements of colour are sufficient for many purposes. For example in colour photography we need to know whether or not the reproduction looks like the original, or by how much it differs. The following sections describe some of the physical measurements that are used for this objective description of colour.

Spectral Reflectance Data. It is well known that "white" light is composed of all colours of the spectrum. If we shine this white light on to a surface the surface will look, say, green because it reflects more of the green component of the light than of the others. If we shone a red light on to the surface it would appear black because it does not reflect red light. The surface itself has not changed in its ability to reflect light in a certain way. It is the change of illuminant that has caused the apparent change in colour.

By measuring the proportion of light that a surface can reflect at each wavelength of light throughout the spectrum, and combining this information with the spectral energy distribution of the source, we have a means of specifying objectively the colour of the surface. The reflectance (or transmission in the case of transparent media) is normally expressed as a percentage of the incident light at each wavelength, and the curve obtained by plotting out the percentage reflectance against wavelength is termed the spectral reflectance curve.

Two surfaces which have identical spectral reflectance curves will always look the same when viewed side by side. But under certain conditions it is also possible for two surfaces of different spectral reflectances to look the same. These are called metameric colours. For example a surface which reflects only yellow light will appear yellow, but so will a surface which reflects both red and green light only. Viewed in "white" light they may look the same but viewed in red light one will appear black, the other red.

Spectral reflectance measurements do not provide immediate information on the appearance of a surface colour—they are not intended to. They are of value because they specify an intrinsic property of the surface alone. In order to obtain from them some idea of the appearance of the surface, spectral reflectance curves can be combined with colour mixture data for plotting on a C.I.E. or similar colour diagram.

Colour Mixture Data. A wide range of colours can be obtained by adding red, green and blue lights in various proportions. The intensities of each light required to match a given sample provide a measure of the colour of the sample.

For highly saturated samples it is not always possible to obtain a match directly by the addition of the three lights. In such cases it is however possible to desaturate the sample by adding one of the lights to it and then matching the result with the other two lights. The light added to the sample is thought of as a negative addition of light. Expressed mathematically we can say, for example, that

Sample + Red = Green + Blue
or Sample = Green + Blue − Red

It is possible in this way to find the amounts of the three lights required to match each of the pure monochromatic lights throughout the spectrum. By plotting these amounts against wavelength we obtain a set of colour mixture curves. Strictly they are colour mixture curves for the eye, as the eye is used to match the two patches of light. We are, however, still dealing with objective colour measurement. The eye is used here purely as an instrument to determine

COLOUR MIXTURE CURVES: The values of x, y, z are the amounts of the C.I.E. imaginary primaries required to match a unit amount of energy for each monochromatic light throughout the spectrum. They are plotted here as tri-stimulus values against wavelengths.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

a colour match, and colour mixture curves are not intended to give a subjective measure of colour. The colour mixture curves obtained depend on the energy distribution of the source of the "white" light, e.g. different curves would be obtained for tungsten light and daylight as the source.

There is nothing unique about the three lights used to obtain these curves. There is an infinite choice of lights that could be used. They need not be confined to any particular wavelengths, they need not be monochromatic. The only criterion is that it must be possible to obtain white by direct addition of all three lights in suitable proportions. The lights used to obtain a particular set of mixture curves are called the primary colours for the system.

The colour mixture curves for any set of real primaries always involve negative parts of the curves. These negative components complicate any calculations with the mixture curves. In order to simplify calculations we need a set of all positive mixture curves. These can be obtained mathematically by calculating such a set of curves from the mixture curves of a real set of primaries. The primaries that must be used for such mixture curves are imaginary colours.

The use of imaginary quantities is common in science as there are many cases where calculations are simplified by their application. An imaginary colour is no more unusual than any other imaginary quantity. To give some meaning to the concept we may think of an imaginary colour as being one with a higher saturation than any obtainable colour. The most highly saturated colour that can be obtained in practice is a monochromatic colour. We can conceive of colours more saturated than this just as we can conceive of speeds in excess of the speed of light—the highest speed obtainable in practice. (N.B. There are exceptions to these statements in both colour physics and relativity physics.)

The C.I.E. System. One set of colour mixture curves based on imaginary primaries is accepted as an international standard. This is the set adopted by the Commission Internationale de l'Eclairage (C.I.E.).

The basic light source for the C.I.E. system is an equal-energy source, that is, one that has equal output energy at all wavelengths, and the basic colour mixture curves are those required to match a unit amount of energy at all wavelengths. A number of subsidiary light sources are specified, each designed to be typical of the more commonly used sources.

It is possible to convert the basic colour mixture curves to suit these sources as required. The amounts of the primaries required to match a colour are called tristimulus values, and denoted by $\bar{x}$, $\bar{y}$, $\bar{z}$ for monochromatic light in the C.I.E. system. A feature of the C.I.E. mixture curves is that the primaries are so chosen that the $\bar{y}$ curve is identical to the luminosity curve of the eye. (The eye is that of

C.I.E. CHROMATICITY DIAGRAM. This shows the spectrum locus and the locus of purest purple (connecting line between the points corresponding to 4,000 and 7,000 A). All real colours lie within these loci. G is a green viewed in an illuminant whose colour is plotted at C against the white point or achromatic point. The dominant wavelength of G is 5,200 A and its excitation purity is 75 per cent. Luminance would be a dimension at right angles to the plane of this diagram, with its axis erected at C.

the C.I.E. "standard observer"—obtained by averaging the results of a number of observers.)

To find the tristimulus values for a non-monochromatic colour, the transmission curve (T) for the colour is combined with the colour mixture curves (modified for the particular illuminant being considered). This is done by multiplying the curves $\bar{x}$ with T, $\bar{y}$ with T, $\bar{z}$ with T, wavelength by wavelength and then adding the results throughout the spectrum in each case to obtain three numbers X, Y and Z. These numbers then indicate the amounts of the primaries which would be required in an additive mixture to match the colour.

These three values can be modified to a form suggestive of colour appearance. We can abstract the redness, greenness and blueness of the colour from them by taking respectively the values

$$x = \frac{X}{X + Y + Z} \text{ (approximately redness)}$$

$$y = \frac{Y}{X + Y + Z} \text{ (approximately greenness)}$$

$$z = \frac{Z}{X + Y + Z} \text{ (approximately blueness)}$$

In this way we reduce all colour to a common function since

$$x + y + z = 1$$

for all colours. It is also true from this equation that if we know x and y then z is automatically defined. For example if x is nearly equal to 1 then both y and z must be small and the colour is red: if x and y are both small z must be nearly 1 and the colour is blue. When x, y and z are all nearly equal to $\frac{1}{3}$ the colour is close to "white" since it has no predominant hue.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

A diagram which plots x against y is a chromaticity diagram. Such a diagram has a horseshoe-shaped graph which is the locus of all monochromatic colours, that is, it is the spectrum locus. The straight line joining the ends of the horsehoe is the locus of purest purples, i.e. it represents combinations of the extreme red and blue monochromatic colours.

In the C.I.E. chromaticity diagram the resultant of the addition of any two colours lies on the straight line joining them. One particular case of this is that any colour may be thought of as being on the line joining a spectral colour and the "white point" (the point on the diagram representing the illuminant colour used to view the colour itself). The wavelength of the spectral colour used is called the dominant wavelength for the colour. The position of this colour on the line depends on the proportions of the spectral colour and the white needed to obtain the colour. This proportion may be expressed as the ratio of the distances of the colour and of the spectral colour from the "white point". This ratio is called the excitation purity of the colour.

The similarity to subjective colour diagrams is apparent if we think of dominant wavelength as being roughly equivalent to hue, and excitation purity as roughly equivalent to saturation.

The third dimension in the C.I.E. system is luminance. The value of luminance is in fact the value Y. This derives from the fact, mentioned previously, that the colour mixture curve for $\bar{y}$ is identical to the luminosity curve of the eye. Luminance is comparable with the subjective dimension of luminosity.

The C.I.E. diagram is particularly useful for calculations in additive systems. Its use is not confined solely to such systems, however, as it is one of the few methods available for precise objective measurements of colour. Strictly the C.I.E. system is designed for illuminant colours but is again extended to cover surface colours as well.

Other Systems. Only a few of the other valuable systems can be mentioned here.

The Ostwald surface-colour system, originally published in 1917, is now represented by a collection of over 900 mat and glossy colour samples in the *Colour Harmony Manual.*

The calibrated coloured glasses of the well-known Lovibond subtractive system continue to be useful in conjunction with the Tintometer for evaluating either reflecting or transmitting samples.

The I.S.C.C.-N.B.S. (Inter-Society Colour Council—National Bureau of Standards) system of designation consists of over 300 meaningful and carefully related colour names representing corresponding blocks of Munsell colour space which are small enough for many purposes.

Among the colour dictionaries is that of Maerz and Paul which contains 7,000 printed colour samples many of which are correlated with common colour names.

Ridgway's earlier series of over 1,000 fully-named samples was recently restandardized.

Villalobos's recent colour atlas of over 7,000 small colour samples is characterized by unusually good spacing.

There are available numerous coded sample collections for more special applications, such as the Horticultural Colour Chart of over 1,000 samples for evaluating and comparing flowers; others are for agricultural products, textiles, paints, printing inks, plastics, etc.

Various useful colorant-mixture systems have been devised. Such systems commonly provide series of colour samples together with formulae for reproducing their appearance by admixture of several standard paints or other colorants. Similarly, subtractive colour photography depends on sets of standard cyan, magenta, and yellow dyes, though these are combined in layers rather than by physical mixture.

COLOUR PHOTOGRAPHY HISTORY

The historical development of colour photography could be divided into two periods, each guided by a basic philosophy entirely different and independent of the other. In one, called objective colour, an attempt was made to produce the same conditions in the image which caused the original object to be coloured. In the other, subjective colour, the attempt was made to produce conditions in the image which created the same colour sensations as did the original. The first concept held sway from the earliest days up to the close of the nineteenth century. The second, introduced in 1855, was not accepted until 1890, but from then on it became the basic philosophy for all subsequent work.

Objective Colour Photography. An object appears coloured if it preferentially absorbs some of the light rays falling upon it. Every colour is characterized by a definite pattern of absorptions for specific rays, i.e., its absorption spectrum. To match one colour with another, the matching colour must have an absorption spectrum identical with that of the colour under consideration. In colour photography this matching must be done for each image point. Processes which accomplish this form the class of objective colour processes.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Interference Processes. The starting point for such procedures lay in the disclosures of Johann Seebeck. In a letter to his friend Goethe in 1810 he reported that silver chloride, upon exposure, took on the colour of the exposing light. This observation became the basis for the researches of others, notably Edmond Becquerel and Niepce de St. Victor.

In their experiments they exposed a specially treated layer of silver chloride under a colour original. The image formed appeared to be coloured in hues approaching those in the original. Zenker gave a plausible explanation for this in 1868. He reasoned that when light was incident upon the layer of silver chloride, it passed through the layer and became reflected by the white paper backing upon which the light sensitive material was coated. This caused the formation of standing waves. At the nodes, the forward and backward beams cancelled each other, but at the anti-nodes they supplemented each other. At these points the light intensity became sufficient to cause photochemical decomposition of the silver chloride. Hence through the depth of the layer were formed lamina of silver, whose distances apart were half the wavelength of the incident light. The lamina served as gratings and interference patterns for any subsequent light incident upon them, with a resultant reproduction of the wave pattern of the original.

In 1890 Otto Wiener pointed out that it should be possible to replace the silver chloride layer with a fine-grained photographic emulsion. This would enable the operator to fix the images and thereby achieve permanency. The actual work was accomplished by Gabriel Lippmann, the following year. The process is now known as the Lippmann interference procedure.

The experimental evidence that colour was produced as a result of optical interference came in 1907, when Cajal reported upon a study he made upon the Lippmann process. Sections made through an image showed the presence of lamina. These averaged from four to eight in number, though occasionally, especially in areas of bright saturated colours, as many as thirteen were noted. Whites and achromatic colours gave diffuse images. A Lippmann slide had to be viewed normally, and by the light reflected from a mirror placed in contact with the emulsion side of the slide. This created many difficulties of operation, and served as a drawback to its further development.

Dispersion Processes. An entirely different solution was devised by Lancaster in 1895. The image of the object being photographed was broken up into a series of points by means of a screen similar to a process screen used in block-making, placed in the focal plane of the camera lens. A second lens brought each image point to a focus upon a prism with an angle of the order of 2° or 3°. The prism saw the image only as a series of point sources of light, each of which was dispersed into a spectrum. In contact with the prism, a fine-grained photographic emulsion recorded the minute spectra. The final image was a series of minute deposits of silver, each a record of the quantity and quality of the light registered at that point.

To re-create the image in colour, a positive of the record was placed between two prisms, identical to the one used in the original photograph, and positioned complementary to each other. The combination, in effect, formed a glass plate with parallel sides. On the side facing the light was placed a screen identical to the one through which the photograph was taken. On directing a parallel beam of light upon the screen, the picture area was broken up into point sources of light. Each point, upon traversing the first prism, became dispersed into a micro-spectrum. With correct registration between screen and positive, each micro-spectrum fell upon an image point in the positive, and became modified by it. The second prism reformed the modified beams. Thus the quality and relative quantity of the original light was recreated at each point of the image.

The process had to record properly the complete spectral distribution and intensities of the incident rays in minute areas, therefore only very fine grained and thus extremely slow emulsions could be used. Exposures of the order of a fraction of a second normally used in everyday photography were out of the question. For this reason objective colour systems reluctantly gave way to subjective systems.

Subjective Colour Photography. The present practice of colour photography is that of trichromatic or subjective colour reproduction. In 1802 Thomas Young promulgated the hypothesis that colour was a sensation. His main thesis was that the sensation produced by any one colour could be matched by that produced by a suitable mixture of three fundamental colours called primaries. From this point of view every colour could be conceived as being formed of some combination of the three primaries.

To duplicate a colour, it was necessary and sufficient to form a colour with the same relative intensities for the three primaries. The problem, therefore, was to determine the relative intensity of each primary in a given colour and then re-form it.

The first to suggest a method to accomplish this was James Clerk Maxwell. In 1855 he suggested the use of optical filters to isolate each primary, and the use of the photographic process to determine their intensities, point by point in a given scene. At a subsequent lecture, in 1861, he gave a demonstration of the process.

The experimental work was done by Thomas Sutton, a prominent photographic practitioner of that era and editor of the magazine *Photographic Notes*, where he published a detailed

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

account. He made three exposures, one each through a red, green and violet filter. He then projected these images, as positive transparencies, in register with each other upon a white screen. Each was illuminated with the same coloured light to which it was exposed in the camera. The result was not exactly breath-taking. It was described by Sutton in these words, " . . . and when these different coloured images were superimposed upon a screen, a sort of photograph of the striped ribbon was produced in natural colours."

Maxwell in fact prepared a fourth plate exposed through a yellow filter; this was intended as a possible alternative to the red filter negative, but was apparently not used in the actual experiment.

Though disappointed with the result, Maxwell and Sutton had made and disclosed one of the most fundamental of all photographic discoveries, and laid the foundations of trichromatic colour photography.

Nevertheless for a hundred years Maxwell's demonstration remained something of a mystery, because at that time no photographic plates were sensitive at all to light of longer wavelength than blue, and therefore separation negatives in green and red light were impossible. The solution of the mystery was given in the centenary year, 1961, when Evans showed that the three negatives had actually been exposed to different wavebands in the blue, violet, and ultra-violet regions. Unknown to Maxwell or Sutton, the filters used happened to transmit these bands, which enabled true separation negatives to be obtained, aided by the fact that the spectrum of the red cloth which was photographed almost certainly had a secondary reflectance band in the ultra-violet.

The subject took a fresh start in 1868, when Ducos du Hauron proposed a solution based upon the same principles previously disclosed by Maxwell. He was, however, completely unaware of Maxwell's contributions. He went further than Maxwell. He outlined a number of other techniques by which colour reproduction could be achieved. Unlike Maxwell, he continued to write and lecture upon trichrome colour photography.

Slowly the popular prejudice against subjective processes wore down, but it was not until 1890 that they were finally dissipated. Further progress concerned itself mainly with the disclosure of procedures that were practical utilization of the fundamental principles disclosed by Maxwell and du Hauron.

The processes could be grouped into three classes. These were:—

(1) Processes which utilized additive colour analysis and colour synthesis;

(2) Processes which utilized additive colour analysis but subtractive colour synthesis; and

(3) Processes which utilized subtractive colour analysis and colour synthesis.

Additive Analysis and Synthesis. The very first demonstration of colour photography, that made by Maxwell before the Royal Institution in 1859, was an example of additive colour analysis and synthesis. In additive analysis each colour record or separation, to use more technical language, is formed from the whole light reflected from the subject. The primary desired is selected by the use of an optical filter which transmits but a single primary. The other two are absorbed by the filter in question, and are therefore lost or wasted.

In additive colour synthesis, the image is re-formed by projecting a positive transparency from each separation in register with the others, upon the same surface, each illuminated by the light of a single primary colour. The re-formed image consists therefore of the additive mixture of the primary coloured lights; hence the name.

A much simpler procedure to achieve the same result was described by du Hauron, in his French patent of 1868. He divided the image into a series of minute image points, by the use of a screen placed in the rear focal plane of the camera lens. The elements of the screen were primary coloured dots or lines, which completely filled the screen area. The size of the dots was such that the eye was unable to distinguish them individually, but saw only a blend. Although the dots were coloured red, green, and blue, the eye saw the blend as colourless or grey. Immediately over the screen was coated a panchromatic photographic emulsion. The exposure was made through the screen elements. Therefore the intensity of the red primary reflected from any point of the scene became recorded as a silver density immediately below a red dot at the corresponding point in the image.

On reversal processing, the silver deposit behind each coloured dot reduced the intensity of the light incident at that point to a value needed to reproduce the relative intensity of the primary in question. Thus only a single exposure was required to made a complete analysis of the scene. By the same token, only a single projector was needed to effect colour synthesis. The net result was that the beam of light reflected from each point of the object was divided into three sub-beams, and each passed through a filter which transmitted but a single primary colour.

The loss of light in this system was very considerable. The division of the beam into three meant a loss of two-thirds of the available light. The use of a filter which absorbed at least two-thirds of the light incident upon it meant the loss of another two-thirds. This was the main fault to be found with additive processes.

The first commercial additive screen plate was marketed by Lumière in 1907. The screen consisted of a mixture of dyed potato starch grains spread on to a sheet of glass coated with

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

adhesive. The gaps between the grains were then filled with carbon black. Later materials used dyed globules of resin which were rolled to bring them into good contact without gaps.

With this type of screen thorough mixing of the dyed grains before coating was expected to yield a completely even distribution of the filter elements. Practical observation, and later on theoretical calculation, showed that a certain degree of clumping of grains of the same colour is inevitable. The reason is that in a random distribution there is an equal chance for, say, a red grain to be next to a blue, a green, or another red grain. Similiarly, there is a certain though decreasing statistical probability for three, four, five, or more red grains to come together. Microscopic examination even revealed grain clumps of 20 grains of the same colour for which again there is a very small but definite statistical probability. Visually, therefore, such a grain screen appears much coarser than suggested by the size of the grains.

A completely even arrangement of the filter elements is obtainable only in a regularly patterned screen—the exact opposite of a random distribution. The first commercially successful screen plate with a mechanically ruled screen was the Finlay plate of 1908. A few years later a modified process appeared, using a separate screen which was placed in contact with a panchromatic plate before exposure. After processing and printing as a positive transparency the plate was bound up with a similar screen of filter elements for viewing. This method enabled any number of colour positives to be produced from one exposure.

Around 1930, additive colour materials with a printed screen or reseau also appeared as roll, miniature, and cine film (Dufay). One attempt was made to develop a negative-positive additive colour process, using a negative and a positive screen film. Special printing arrangements were necessary to prevent interference between the screens of the two films.

A special type of screen process was the Kodacolor lenticular cine film, marketed in 1928 and based on patents of 1908. The back of the film support was embossed with minute lenses which, in conjunction with a striped filter in front of the camera lens, broke up the image into large numbers of coloured strips or bands. On projection of the reversal positive through the same striped filter, the colour image was synthesized on the screen.

Additive Analysis with Subtractive Synthesis. The practical needs of colour photography soon found the purely additive processes much too costly, in so far as light was concerned. This became increasingly apparent in cinematography, where it was essential that the three primary impressions be formed instantaneously and simultaneously. This was possible with the screen processes, but these were severely handicapped by the demands of definition. Other technological difficulties existed, especially the ease of accurate and satisfying duplication.

It was this last that turned attention to another of du Hauron's many disclosures, that of subtractive colour synthesis. This was accomplished by the conversion of each primary selection or colour separation into a positive formed of a dye which absorbed a single primary, absorbed it sufficiently so that the residue was the amount needed for colour duplication. Each image point, therefore, consisted of a mixture of three dye deposits, each subtracting sufficient of a single primary to leave the amount needed for duplication.

Colour analysis was still achieved by the additive methods. Special cameras were constructed in which optical devices situated behind the camera lens divided the lens beam into three sub-beams. An optical filter then filtered each beam to transmit but a single primary. In this manner three separations were made, each on a different piece of photographic material.

This created the problem whereby the separate primary records could be converted into dye positives, which could be superimposed one upon the other in exact register. A long era in the history of colour photography concerned itself with that problem. Many ingenious devices were disclosed to accomplish the desired result, but of all of these, just two have achieved widespread popularity, imbibition and carbro.

In the carbro process three separation positives are formed by selective tanning (via bromide prints) of pigmented gelatin foils. On treatment with hot water, the untanned gelatin is washed away, and pigmented yellow, magenta, and cyan images remain. These are then superimposed in register.

In the imbibition methods, first applied to colour printing in 1925 by Jos Pé, three positives are again made by selectively tanning gelatin layers followed by washing out in hot water. That leaves a set of matrices (one for each separation image) which are dyed in dye baths of the appropriate colour and printed in register on to a galetin coated paper.

This is the basic principle of the Technicolor process of cinematography.

Subtractive Analysis and Synthesis. Since it was possible to synthesize the colour image with no loss of useful light, it became desirable to do the same in the analytical part of the process. The first to suggest a method to accomplish this was again du Hauron. He suggested that it should be possible to prepare systems that were sensitive to but a single primary colour. Three such systems in the form of a pack, could be placed in the focal plane of the camera, one immediately behind the other. Each primary colour would register upon one of the three elements. Each could be processed to yield a positive image in the appropriate colour for

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

subtractive synthesis, then joined together to form a single unit, the colour photograph of the original. In these procedures each primary was recorded and duplicated upon a separate piece of photographic material. These had to be joined together somehow, to re-form the whole.

In 1912 Siegrist and Fischer disclosed a new photographic procedure that converted the latent image directly into a dye image. The oxidation product formed when exposed silver halides were reduced to form the silver image was highly reactive and capable of union with other substances to form yellow, magenta and cyan dyes. It was possible to add such ingredients, colour formers, to each emulsion, so that the blue sensitive element could yield a final yellow dye image (blue absorbing), the green sensitive element a magenta dye image (green absorbing) and the red sensitive element a cyan dye image (red absorbing), all by the use of the same developing agent. Therefore it became possible to form a photographic material in which three light-sensitive emulsions were coated one over the other, with filters between them to insure that each element would be acted upon by the light of but a single primary. Each of the three elements contained the proper colour former so that upon processing a yellow image was formed in the blue sensitive element, a magenta in the green, and a cyan in the red. In this process both analysis and synthesis were accomplished by subtractive methods, with a minimum loss of available light.

A commercial film material based on this principle appeared as early as 1914, but utilized only two colours. Faithful reproduction of the full range of natural colours was therefore impossible.

Siegrist and Fischer's system had one major drawback: the colour formers tended to "wander" from their respective layers. The first integral subtractive tricolour taking material, Kodachrome (introduced in 1935), therefore did not incorporate colour formers in the emulsion layers at all. Instead, each layer was processed separately (although coated on the same support as the other two layers) by a complicated technique involving many carefully controlled stages.

The first commercially available colour film with couplers incorporated in the emulsion layers appeared in 1936 under the name Agfacolor. Two methods have been used to prevent the couplers from wandering from their layers. One was to adsorb the coupler substance on insoluble resin particles or oily media, which effectively anchored the coupler. Another trend has been the development of giant coupler molecules which are in themselves sufficiently immobile not to wander.

Both Kodachrome and Agfacolor were reversal processed, producing a positive colour transparency in the film originally exposed in the camera. Duplicate transparencies could be made by rephotographing the transparency, and materials of this type were introduced first with an opaque plastic base and later with a paper base, for making reversal colour prints.

In 1939 a subtractive colour film was introduced which utilized a negative-positive system. The film was developed to a colour negative in complementary colours, and that was in turn printed on to a positive material to produce a colour print. Designed originally for cinematography, this system soon became a very widespread method of producing colour photographs on paper. Its special merit is the possibility of this type of process being carried out by the skilled amateur photographer at home.

A further development of subtractive colour photography was the use of masks to improve colour rendering, followed in 1950 by the introduction of a colour negative film (Kodacolor) incorporating coloured couplers which act as integral masks for printing.

Other Dye Systems. The great majority of colour materials available today use colour development systems in which the dyes of the image are actually synthesized in the layers. There are in fact two other methods of forming colour pictures; in both of these the dyes are present in the material before exposure. During processing the dyes may be either destroyed selectively, or transferred selectively to another support.

In the first case, the conventional three emulsion layers sensitive to red, green and blue light are coated. Each, however, contains a dye of the appropriate complementary colour (e.g. the red sensitive layer is dyed cyan). After exposure and negative development in a conventional black and white developer, the silver image is used to bleach the dyes in proportion to the amount of silver present. The bleach bath is a strong acid, and may be thought of as dissolving the silver and liberating hydrogen which reduces the dyes to colourless soluble compounds removed by washing. In practice complexing agents and catalysts are also required for a practical process. Since the dye is destroyed in proportion to the amount of the negative silver image, the resulting photograph is automatically a positive. These silver-dye-bleach systems are all based on early patents by Christensen from 1918 and by Gaspar in the 1930's who first made such materials commercially available as Gasparcolor.

The other process is of much more recent introduction. The subtractive tripack is coated with the dyes in adjacent layers, and these are not the ordinary azo-dyes of the dye bleach process, but special dyes which can also function as developers. After exposure, the material is treated with an alkaline solution and under these conditions the dye developers become mobile and develop the exposed silver halide. In doing so, they are of course oxidized, but at the same time their mobility is destroyed and

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

the dye remains fixed in the layer. Where no exposure has taken place, the dye continues to move and finally migrates to a receiving sheet which is pressed in contact with the surface of the material. Here the dye is fixed by a mordant and an acid layer stabilizes it and prevents further migration by neutralizing the alkali. Since dye migrates where there has been no exposure, a positive picture is obtained on the receiving layer. In practice the alkali is contained in a pod ruptured by pressure rollers on withdrawal from the camera. The contents are thus spread between the negative and positive sheets which are separated after an appropriate time interval for development and dye migration to occur; this is the Polacolor system.

In recent years there has been an enormous increase in the use of colour photography and a steady improvement in colour rendering, speed, and resolution of films. The transparency reversal process remains probably the most widely used type of colour photography, but the negative-positive process giving colour prints on paper is increasingly popular. Prints are exposed to light for much longer periods than are transparencies and this fact has emphasized the need for improved light fastness in the dyes used.

Progress has indeed been striking in the past fifteen years and there has been a vast increase of devotees in the field of colour photography. Whereas a generation ago the practice of colour photography required the use of a very expensive and delicate camera, and required the knowledge of very intricate and difficult processing techniques, today every camera is a colour camera, and almost every photographer a potential colour photographer.

COLOUR PRINTING TECHNIQUE

In the early days of colour photography, the only practical way to make a colour print was to photograph the original scene three times on a panchromatic film or plate, once through each of three differently-coloured filters, and prepare a black-and-white print from each of the negatives obtained. Next, each print was dyed a different colour and the three coloured images obtained were transferred in turn to a final paper support, giving the finished print. The process was lengthy and costly, for three negatives and three prints had to be prepared for each final picture, and the problems of registration (making sure that one coloured image lay exactly on top of another) were severe. It is not surprising that colour printing by this method was limited to specialists, despite the very attractive results which could be obtained.

With the advent of tripack material, however, almost all the problems were swept away. For the tripack, as its name implies, combines all three negatives on one sheet of film and all three prints on one sheet of opaque white material, usually paper. Tripack material is so simple to use that nowadays all colour photographs are taken with it, whether to produce colour negatives or transparencies, and almost all colour prints are made on it.

In essence, tripack material consists of three layers of ordinary photographic emulsion on a suitable base, sensitized in effect to blue, green and red light respectively. During processing, complementary dye images (yellow, magenta and cyan) are produced together with the black silver, which is then removed to leave only a picture in the dyes. The mechanism of image formation is thus largely the same as with tripack colour film.

The usual sequence of coating the layers is blue-sensitive on top, green-sensitive beneath and red-sensitive on the bottom. This is necessary with films to enable the blue-sensitivity of the lower layers to be neutralized by a yellow filter layer. In printing, the light used for the exposure is deficient in blue and the sensitivities of the two remaining layers can be so adjusted that their blue-sensitivity can be disregarded. Some manufacturers have therefore changed the order of the layers to secure a sharper-looking picture. So the red-sensitive layer may be on top, the green-sensitive layer in the middle and the blue-sensitive layer on the bottom. The printing and processing of the paper is not affected in any way, whatever the sequence.

Paper types. There are two kinds: positive and reversal paper. Positive paper is for printing from colour negatives which, being only a means to an end, can be made to suit the paper, regardless of the appearance of the negatives. This allows the film manufacturer considerable scope, for he can incorporate in the film emulsions dyes designed to overcome the deficiencies of photographic dyes. This accounts for the orange or yellow "masks" which characterize certain makes of film.

Reversal paper is for making prints from transparencies which allow of no such latitude, for transparencies must look correct if they are to fulfil their basic function. This precludes the use of any masking dyes, and it is more difficult to achieve good colour reproduction in prints made on reversal paper, because of the deficiencies of the dyes in both the transparency and the print.

Printing and Enlarging Equipment. To produce good colour prints from colour negatives

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

requires no special skills and little special equipment not already available for black-and-white work. Owing to the difficulty of working with small pieces of paper in almost total darkness it is hardly ever worth while making contact prints. Colour prints are therefore implied to be enlargements.

Any enlarger will do but it should have a tungsten light source, for fluorescent light can lead to unnecessary difficulties when trying to produce a correctly-balanced print. It should also ideally have a filter drawer in which can be placed coloured gelatin foils whose function is explained below. The enlarger should be quite steady to avoid movement during the exposure, and of course a timer and a holder for the paper being printed are also necessary.

As fluctuations in mains voltage affect both the colour and intensity of the light, some form of voltage regulator should be installed. In its simplest form this consists of a voltmeter and rheostat which enables the voltage to be adjusted to a standard value immediately before making each exposure. The maximum variation of voltage permissible without seriously affecting results is about ± 2 per cent, i.e., ± 4 volts when working at 200 volts. For continuous printing, of course, some form of voltage stabilizer is essential.

The majority of good-quality enlarging anastigmats are suitable for colour work but the colour reproduction is very much better if they are coated (bloomed). An uncoated lens is likely to give considerable softening and degradation of the colours.

Stray light from the lamphouse, negative carrier, etc., must be carefully avoided and the enlarger should not be used close to a light or shiny wall which may reflect light on to the paper during exposure.

The darkroom should also be well blacked-out for colour paper is rather fast, and stray light will almost certainly fog it. As the paper is sensitive to light of all colours, a special darkroom safe light (made by most manufacturers for their colour paper) is necessary. This gives a small amount of light of a colour to which the eye is more sensitive than the paper, but the latter must still not be exposed freely to the safelight.

Filters. Ideally, one should be able to photograph a scene on a piece of colour negative film, process the film and put it into an enlarger and from this make a colour print merely by giving a simple exposure. Unfortunately, there are many reasons why this will not produce a perfectly balanced print; that is, one which is not too blue, nor too green nor with a tint or cast of some other colour. Variations in the colour of the light when the picture was taken, in the colour temperature and age of the enlarger lamp, the age of the processing solutions, and of the paper and film itself—all are liable to affect the colour balance of the print. So we need some method of controlling the colour of the light coming through the negative

COLOUR COMPENSATING FILTERS. These curves show the densities of a typical set of cyan, magenta and yellow filters used to modify the balance of colour prints made from colour negatives by the white light exposure method.

at the printing stage. This is done with coloured gelatin filters, which are placed either above the negative in the lamphouse or immediately below the enlarger lens. In either case they modify the colour of the light reaching the paper.

They thus also modify the colour response of the enlarging paper. If a colour print is too yellow, this is due to too strong a dye image being produced in the yellow-forming (blue sensitive) layer—so this blueness must be reduced. A yellow filter, which absorbs blue, can do this. A pale yellow filter is sufficient if the print is only slightly too yellow; if the yellow cast is strong, then a deeper yellow filter is necessary. Thus a graduated series of yellow filters can correct all yellow casts. Similarly, predominant magenta tints or casts can be removed by a series of magenta filters which progressively hold back green light affecting the green-sensitive layer responsible for the magenta component of the image. Cyan filters in the same

way control blue-green or cyan casts by reducing the red light reaching the red-sensitive layer of the paper.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

This leads to the important rule that a colour cast is removed by a filter of its own colour. That rule also applies to casts of other colours: blue, red and green. Excess green in a colour print is due to too strong images being produced in the cyan-forming (red-sensitive) as well as the yellow-forming (blue-sensitive) layers. Hence both red and blue light must be held back and a cyan and a yellow filter are required for correction. (Cyan plus yellow make green, so the cast is again removed by a combination of filters yielding its own colour.)

In the same way a blue cast is removed by a combination of magenta and cyan filters and a red cast by a combination of magenta and yellow filters. Nor need the combination of filters be of equal strength: a cast may be yellowish-green, indicating that its yellow component is stronger than its cyan component so that the yellow filter in the combination must be denser than the cyan.

This method of colour printing, requiring a set of graduated filters each of the three colours, yellow, magenta and cyan, is referred to as subtractive or white-light printing. It calls for at least four filters of each colour, though in practice manufacturers may produce a series of up to eleven graduated filters of each colour. Prints can be made quickly by this method, once the correct filters have been determined; they are then merely put in the filter drawer and an exposure made in exactly the same way as in black-and-white enlarging.

An alternative method of printing calls for less filters. This is three-exposure or tricolour printing. Here, only three dense filters are necessary: blue, green and red. An exposure is first made through the blue filter; this affects only the blue-sensitive layer and hence is responsible for the yellow image. Without moving the enlarger, an exposure is now made through the green filter which affects the green-sensitive layer and hence produces the magenta image. Still without moving the enlarger or paper a third exposure is made through the red filter. This affects only the red-sensitive layer and yields the cyan image. The print is processed and, if the exposures have been correct through each filter, a perfectly-balanced print results. If there is too much yellow, the exposure through the blue filter is reduced, if too little yellow the exposure is increased, and so on.

Where economy is the sole consideration, and colour prints are required only occasionally, the three-exposure method has the advantage that it requires the purchase of only three filters to start producing colour prints. But it is slow and tedious, for three comparatively long exposures must be given for each print. Also, the enlarger and print must remain steady between and during exposures, otherwise the colour images in the print will be out of register, with consequent general fuzziness and lack of fine detail. When a whole roll of film or more is to be printed the white-light method is to be preferred, as this requires only one short exposure for each print, and twelve prints can be made in the same time as one or two done by the tricolour method.

A further advantage of the white-light method is that the print can be dodged or shaded by the use of a sheet of black card exactly as in black-and-white printing. This is not practicable with tricolour printing as the shading has to be done three times, once while each filter is being used, and it is difficult to keep the three shaded areas in register. In practice, however, dodging or shading is rarely necessary in colour printing.

White-Light Printing. Apart from the colour balance of the colour negative, the filtering required for a correctly balanced print depends on the enlarger itself and on the colour balance of the paper. Manufacturers frequently specify the latter from batch to batch, indicating the deviation from a standard balance in terms of a basic colour correction. A first test print is therefore made, using the basic correction filter in the enlarger plus an ultra-violet filter recommended with some types of paper. Make a stepped print, giving a series of increasingly long exposures, say 2, 4, 8 and 16 seconds. Process the print and examine it when it is dry. Decide on the cast which is present in the step which appears to be about right in overall depth.

Think of the cast in terms of yellow, magenta or cyan. If it is yellowish, for example, make a further set of test prints, using yellow filters of varying strength, until a filter is found which just removes the yellow cast. This filter must now be put in the filter drawer and the final print made. It is not necessary to make a separate print for each filter and process it before proceeding; a square of print paper may be divided into four, and a small print made on each quarter of the paper, using four different filters. These filters may be held below the lens, although in this position, if they are not perfectly clean and of a high optical quality, they may affect the definition of the print. This is not important, however, at this stage as only test prints are being made. When the paper is processed it gives four differently-filtered pictures side by side, making comparison simple.

When the yellow cast has been removed, it may be necessary to use a second filter of a different colour, for there may be another, weaker, cast present. This should be removed in the same way. Note that this cast must be weaker than the first, otherwise it would have been dominant, so it will require a weaker filter to remove it.

When this second cast has been removed make the final print. In working with tripack material, only two layers can be out of balance. This means that filters of only two colours are necessary.

If a filter pack ever is found to contain three colours, remove the filter colour of the lowest

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

density together with the same digits of the other two filter colours. For example if the pack for a balanced print consists of a cyan filter of density 30, a magenta filter of density 20 and a yellow filter of density 10 (see below for a meaning of these filter notations), the density 10 in all three filters only adds up to grey and can be removed. In other words the colour correction effect is the same with a filter pack consisting of a cyan density of 20 plus a magenta density of 10.

Filter combinations of all three colours are liable to arise when the filter pack in the enlarger already contains two filter colours as the basic correction for a particular paper batch, and a third colour is introduced to correct the cast in the first test print. From this it follows that a cast can be corrected not only by adding a filter of the same colour as the cast, but also by reducing the filter density of the other two colours. Thus to get rid of a yellow cast you can either put a yellow filter into the enlarger (as explained above), or reduce the density of the cyan and magenta filters if these are already in position. This reduces the predominance of the yellow image by increasing the strength of the other two images.

COLOUR CORRECTION FILTER ADJUSTMENTS FOR POSITIVE PRINTING

Filter Notation. There are two main ways of labelling white-light correction filters. The best known is the CC notation. CC stands for colour correction and the filter notation includes a density value and a letter indicating the colour. The density values range from 05 to 50. Thus the notation CC-50M indicates a magenta correction filter of density 50. (The actual density—to green light—is 0.5, but 50 happens to be a more convenient way of putting it.) Similarly a CC-05Y is a yellow filter with a density value 05 (in fact 0.05.

The complete series in each colour may include the values 05, 10, 20, 30, 40, 50 and even higher ones. Higher filter densities may, however, be obtained by combining two lower ones, e.g. a filter value of CC-80C could be obtained by combining a cyan 50 and a cyan 30 filter. Similarly the 05 step provides intermediate combinations such as 15, 25, etc.

With this notation the complete filter combination for a particular print can be expressed in a form like CC-10M + CC-20Y.

Some manufacturers also produce a series of red, green and blue filters—ranging for example from CC-05R up to CC-50R, and the same way for the blue and green series. These filters behave like combinations of two filter colours in the cyan, magenta and yellow range of equal density. Thus a green filter CC-20G is equivalent to the combination CC-20Y + CC-20C and can be substituted for this filter pair. These red, green and blue filter series are, however, rarely essential.

The second notation dispenses with the letters altogether and uses only a series of six figures. These define individual filters or complete filter combinations. The first two figures are the yellow density, the second to the magenta density and the third to the cyan density. In this notation a filter 00-50-00 corresponds to a CC-50M; the notation 20-10-00 is equivalent to the combination CC-20Y+ CC-10M.

Exposure. Once any colour cast on the correctly exposed step of a test print is corrected, the overall density range will no longer be right. The exposure therefore needs correction as well. This can be done either by a further stepped print with the correct filter combination, or by multiplying the original exposure by the product of the filter factors. The latter vary slightly from manufacturer to manufacturer. Yellow filter factors can usually be ignored, while magenta and cyan ones may range from 1·2 to 2·5 according to filter density.

Some allowance is also desirable for the actual number of filters in the enlarger since each filter results in some light loss by scattering and reflection, quite apart from its colour filtering effect. Usually the exposure should be increased by 10 per cent for every additional filter in the pack or reduced by 10 per cent when the combination is decreased by one filter. One way to eliminate this correction is to have a pack of standard number—for example four filters—and keeping up this number with plain colourless gelatin sheets if fewer filters are required.

In practice, filtering is not so difficult as may appear from the instructions given above. One or two points should be stressed however. Logically, test prints should be made with filters of gradually increasing strength. Make a note of everything that is done, so that it is possible to determine which filter produced a particular result. The information is best written in pencil on the back of the print.

Three-Exposure Printing. This requires three filters, in effect a tricolour set, which should preferably be mounted on a rotating or sliding stage under the enlarger lens so that each can be brought in front of the lens in turn. Care must be taken not to move the paper or negative or to shake the enlarger when changing the

Blue	Yellow	Red and green	Blue
Cyan	Red	Red	Green and blue
Magenta	Green	Green	Red and blue
Yellow	Blue	Blue	Red and green

filters between exposures, otherwise lack of registration and colour fringing may be produced in the print.

The colour balance and density of the print are adjusted entirely by regulating the duration of the three exposures (which must, of course, be determined by trial).

First make a stepped print through the red filter only, giving, say 4, 8, 16 and 32 seconds. After processing, this yields a cyan image. The exposure which gave a section showing the picture clearly yet rather faintly is the correct one.

Next put another strip of paper in the holder and give the whole strip the chosen exposure through the red filter. Without moving the paper give it additionally a stepped exposure through the green filter and process as before. There will now be an overall cyan picture superimposed by a stepped magenta picture. Note the exposure through the green filter giving an exact balance between the magenta and cyan image, that is, a blue picture.

Put a third strip of paper in the holder and give it the chosen red and green exposures and, on top of this, make the stepped picture through the blue filter. After processing, there is an overall blue picture on which is a stepped yellow image. One of these will give a balanced result, not too blue, not too yellow. The final print may now be made using the chosen exposures.

If the final picture is too light, all three exposures must be increased by the same fraction; if too dark, decreased by the same fraction. So, if the exposures given were red 8, green 10 and blue 14 seconds and this was found to be too light, make another print giving red 12, green 15 and blue 21 seconds.

Some care is necessary in the choice of the filters. Each filter should completely hold back light of a colour that might affect layers of the colour paper other than of the same sensitivity as the filter colour. Thus the blue filter must pass only blue light and no red, otherwise accurate colour control becomes impossible. An easy test is to make test strips through each filter in turn on the colour paper in use. After processing the strips should show only the pure colour images (yellow, magenta and cyan respectively) without any tinge of the second dye. If this is not the case, one or more of the printing filters may need an additional colour filter to hold back unwanted colour components.

Colour Grading Aids. The trial-and-error methods outlined above are only suited to very small-scale working where occasional prints are required. When many prints have to be produced daily from different types of negatives, a quicker method is essential. This is done by means of a densitometer, a device which measures the colour of a negative or transparency in terms of its blue, green and red densities. The negative is placed in the densitometer and a reading taken in turn through each of the three filters which are incorporated in the apparatus. By a simple piece of calculation this can be translated into the exposure which need be given through three similar filters, as in tricolour printing, or by a slightly more involved calculation it can be used to show what yellow, magenta or cyan filters are necessary when doing white-light printing.

Densitometer reading requires careful choice of the section of the negative to be read. A simplified densitometer technique measures the average light through the whole negative, in turn through a red, green and blue filter. This is considered to integrate to grey—in other words the negative is treated as if the total light coming through it were neutral and filtered to achieve such a neutral balance. This principle is based on the assumption that the overall colour of average subject in nature is neutral; this is, in fact, valid for about 80 per cent of all cases. For negatives where an integration to grey does not yield a correctly balanced print, the additional correction necessary can be estimated fairly accurately from the first test print.

Another simple aid for colour negative grading is a colour step wedge. This consists of a normal grey wedge of about 18 or 20 steps which has a red, green and blue filter strip laid side by side over all the steps. This colour step wedge is placed on top of a sheet of the colour paper on the enlarger baseboard and exposed to the light from the colour negative which has, however, passed first through a diffuser to provide the grey integration. The lightest visible step in each colour on the print indicates the relative exposures required through the blue, green and red filters for three-exposure printing, or the exposure plus the correction filters required for white-light printing.

Filter Control Aids. Some professional colour enlargers greatly simplify the mechanical selection of filter combinations. Usually they incorporate a colour head in which continuously graduated cyan, magenta and yellow filters are moved into the light path. Alternatively a single high density filter of each colour may be moved into the light to greater or lesser extent, progressively increasing the proportion of the light going through the filter as compared with the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

selection, are identical with those for making colour prints on paper. Judging the exposure is a little different, since the test transparencies have to be held up against a suitable light source—preferably of daylight quality (for example certain blue-filtered tungsten lamps)—to assess the required image density. Processing of positive colour films is also a little different since the emulsions on the film are much more delicate and easily damaged. Positive transparency films are usually processed in sheet film holders which go into appropriate tanks. The basic processing sequence is similar to that for colour paper though the recommended processing solutions and processing times may be different.

Printing from Transparencies. The majority of colour prints are made by printing colour negatives on to positive colour paper. Where prints are required from transparencies, there are two possibilities.

One involves making an inter-negative, which means photographing the transparency on to a special colour negative material and then printing in the normal way. Despite the apparent deviousness of the route to get the finished print, it produces very satisfying results. It is popular with processing laboratories, who prefer its reliability and simplicity to printing direct from the transparency on to reversal paper.

There are two difficulties in direct printing on to reversal paper. One is that colour transparencies have to be balanced for the best visual effect which involves compromises in colour rendering. These shortcomings are further emphasized when the transparencies are printed on to reversal paper.

Further, the contrast of a colour transparency is very much higher than the tone range which a paper print can accommodate. The reversal print made from a transparency therefore tends to lose detail in the highlights and shadows and is liable to show further colour falsifications in these tones. The most suitable transparencies for printing on reversal paper are therefore those of low contrast and with a thin image.

The actual exposing procedure is very similar to enlarging from colour negatives, and corresponding sets of cyan, magenta, and yellow correction filters are employed. The correction applied, however, is different. Excess of any one colour is compensated by reducing the filter density of that colour (or increasing the filter density of the other two colours). Similarly, lack of one colour is compensated by increasing the filter density of that colour.

With tricolour printing the sequence of operations is the same, i.e., if the print is too blue (lacking in yellow) the exposure through the blue filter must be reduced; if it is not blue enough (too yellow) the exposure through the blue filter must be increased.

As with all reversal material, there are two extra processing stages, the first development and the reversal exposure. This adds considerably to the time necessary to produce a test print and makes the process tedious when printing by trial-and-error methods.

CORRECTION FILTER ADJUSTMENTS FOR REVERSAL PRINTING

Print Shows Excess of:	*Print Shows Lack of:*	*Take out (or Reduce density of) Following Filters:*	*Or Insert (or Increase Density of) Following Filters:*
Red	Cyan	Yellow and magenta	Cyan
Green	Magenta	Yellow and cyan	Magenta

Magenta	Green	Magenta	Yellow and cyan
Yellow	Blue	Yellow	Magenta and cyan

Dye Destruction Papers. While most types of colour printing paper form the dye images in the emulsion layers by chemical reactions while the silver image is developing, there are also systems which work in the opposite way. There the three emulsion layers already contain the dyes before the paper is exposed. Again the blue-sensitive layer contains a yellow dye, the green-sensitive layer a magenta dye and the red-sensitive layer a cyan dye. During processing these dyes are *destroyed* and not formed in proportion to the silver image produced. Straightforward processing thus yields a positive from a positive—a print from a colour transparency—while a positive colour print from a colour negative requires a sequence similar to normal reversal processing.

The filtering technique for prints from negatives and transparencies is the same as for conventional negative-positive and reversal printing procedures respectively. The actual filter combinations required for balanced prints is likely to be different from that needed with the conventional system.

The main difference is in processing. For making positives from colour transparencies, the processing steps are development (which forms the silver image), dye bleaching (which removes the dye in the areas where the silver image is formed), silver bleaching, and fixing to dissolve away the bleached silver image. This sequence is very much shorter than reversal processing with conventional colour materials.

When making a positive print from a colour negative, the processing stages are development, silver bleaching (to remove the developed silver image), re-exposure and re-development to form a new silver image in the previously unexposed areas of the emulsions, followed by dye bleaching, silver bleaching, and fixing as before.

COLOUR PRINT PROCESSES

The principle behind colour printing processes is that visible light of any colour can be resolved into a mixture of blue, green and red light in varying proportions. Further, light of any of these three colours can be absorbed by a filter of its complementary (opposite) colour. So blue light can be absorbed by a filter of its complementary colour yellow, green light by a filter of its complementary colour magenta (blue red), and red light by a filter of its complementary colour cyan (blue green). All colour printing processes are based on this rule.

It is customary to refer to the three colours blue, green and red as additive primaries (because light of all three colours added together in the right proportion gives white light) and their complementary colours yellow, magenta and cyan as subtractive primaries, because they are obtained by the subtraction of the additive primaries from white light.

Modern photographic colour printing processes are of three types. One is integral tripack printing which uses a white base coated with three successive layers of emulsion in which three dye images are formed. The second (and oldest) process involves the assembly of a colour print by the superimposition of three coloured images which have been prepared separately. The third type is a variant of the first, using a tripack of three emulsion layers which already contain dyes. The dye pictures are here formed by the image-wise destruction or removal of dye.

Owing to the ease and speed with which prints can be made on tripack material, this has almost completely supplanted the assembly method of producing colour prints photographically.

Integral Tripack Printing Papers. These printing papers work on the same principle as colour transparencies. The three image layers cannot, however, be as dense, because the contrast range is limited to the difference between the amount of light reflected by the white base and the darkest black of which the print surface is capable.

The three layers are sensitive to blue, green and red light respectively, and analyze the light coming from the negative or transparency in terms of these three colours. When the print is processed the three layers produce coloured images in their complementary colours, so that a yellow image is produced in the blue-sensitive layer, a magenta image in the green-sensitive layer and a cyan image in the red-sensitive layer. The colour balance of the print can be easily controlled by using colour filters during printing, but little or no contrast control as between the three colour images is possible.

There are two kinds of integral tripack printing papers; those intended for printing from colour negatives and those intended for printing from colour transparencies.

The colour negative is solely a means to the end because it is a negative with the colours complementary to those of the subject and hence of no value in itself. It is thus possible to include masking dyes in the negative to compensate for any deficiencies in the dyes which constitute the colour negative. Because of these deficiencies in photographic dyes, the negative-positive system of producing prints will give more accurate colour reproduction than direct prints made from a colour transparency. The latter is normally designed to be viewed direct and so, of course, cannot contain masking dyes. There is also the further advantage that neither the negative nor print require reversal; this cuts down the processing to three essential steps—colour development (in which silver images, which are not required in the finished print, are of necessity produced), bleaching (to convert the unwanted silver images back to silver bromide) and fixing (to remove all silver salts).

Reversal papers used for making prints from

TRIPACK COLOUR PRINTING. 1. Subject consisting of Blue B, green G, red R, white W, and black B. 2A. A colour negative film records each colour only in the layer sensitive to it. The dyes formed are complementary to the original sensitivities. 3A. On printing on a positive colour material, the layers are affected in the same way, reversing the colours to form the colour print.

2B. A positive transparency consists of similar colours to a positive print. 3B. To make a reversal print, the material is exposed to the transparency and developed to a negative silver image (shown as solid black). 4B. The unexposed parts of each layer are converted into a colour image, and the silver removed.

DYE DESTRUCTION PROCESS. Top: Positive prints from positive transparencies. 1a. Subject consisting of blue B, green G, red R, white W, and black B. 2a. Exposure and development leads to a silver image in the layers sensitive to the transparency colours. These layers already contain complementary dyes. 3a. Dye bleaching removes the dye image in the areas of the silver image. 4a. The final bleach-fix also removes the silver image, leaving only the dye images.

Bottom: Positive printing from colour negatives. 1b. Colour negative consisting of yellow Y, magenta M, cyan C, black B, and white W. 2b. Exposure and development produces a positive silver image in the appropriate layers. 3b. Bleaching removes the developed silver. 4b. The second exposure and redevelopment produces a negative silver image from the residual silver salts. 5b. The dye bleach removes the dyes in the areas of the silver image. 6b. The final bleach-fix removes the negative silver image, leaving only a positive dye image.

positive colour transparencies require at least five steps for processing; first development, re-exposure to light (the so-called reversal exposure), colour development, bleaching and fixing. Owing to the difficulty of obtaining good whites in the finished print this material is sometimes coated on a white opaque film base instead of on paper.

In dye-destruction tripack papers the three emulsion layers already contain the dyes. The final image is produced by bleaching the dyes in proportion to the silver image formed in each layer. Straightforward processing (development, dye bleaching, silver bleaching) produce a positive picture from a positive transparency. To obtain a positive from a colour negative requires a reversal processing procedure.

Separate Image Processes. In many commercial processes the separate images are made via three separation negatives taken direct from the original subject or from a colour transparency. An exception to this is when separation positives are printed direct from a colour negative on to panchromatic material through red, green and blue filters in succession.

Separation negatives are made direct from the subject by photographing it on to three different negatives through red, green and blue filters respectively. Unless an expensive beam-splitting camera is used, photographs taken by this method are limited to still life subjects. When a positive colour transparency is used as the original, it can be photographed three times through tricolour filters or printed or enlarged in a similar way to yield separation negatives.

Most transparencies have a very great tone range. This fact, coupled with the imperfections of the dyes used in both the transparency and in the final colour print, make it important to apply some kind of correction if the full advantages of the separate image processes are to be realised. By the use of masking—weak negatives made from the transparency and bound in register with it—it is possible to achieve improved colour rendering.

When separation negatives have been made by one of these methods, it is then necessary to produce the final print from them. Many methods were formerly used to achieve this (carbon, Carbro, Duxochrome, dye transfer, chemical toning and dye toning). Nowadays, dye transfer is the only method in common use, although the others linger on in the hands of enthusiasts.

Carbro and Carbon. These two allied colour printing processes are the oldest ones remaining in use today. They are capable of giving a gradation in the highlights and shadows which is seldom equalled and not yet surpassed by other processes.

They depend on the tanning action of chromium compounds on gelatin, and the difference between the two processes lies in the way in which this tanning action takes place.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CARBRO IMAGE FORMATION. 1. Sensitized pigment paper squeegeed into contact with bromide print. This forms a tanned gelatin image. 2. Pigment paper squeegeed on to plastic temporary support. 3. Gelatin relief left after hot water treatment. 4. Relief on plastic support squeegeed on to gelatin-coated permanent support. 5. Final pigment image on permanent support after stripping off temporary support.

In the carbon process the three coloured gelatin images are made by sensitizing specially prepared sheets of pigment paper in a potassium bichromate sensitizer and then printing them directly from the separation negatives. Tanning action takes place in proportion to the exposure and after transferring the pigment papers to transparent supports the untanned gelatin can be washed away in hot water leaving three coloured relief images. These are then combined on one sheet of paper to form the final colour print.

The disadvantage of the carbon process is the very low sensitivity of the pigment paper. This means that it usually has to be printed by contact from an enlarged negative using a special light source such as an arc lamp.

Carbro overcomes this disadvantage but at the cost of an additional step. In carbro three bromide prints or enlargements are made, one from each of the separation negatives, and the tanning action takes place when the wet sensitized pigment paper and the bromide print are brought into contact.

Carbro is, on the whole, an easier process for the amateur particularly as the bromide prints give a useful visual guide for exposure and colour balance. The definition is not quite up to that of carbon because the tanning action is caused by diffusion of the chemicals between the pigment paper and the bromide print. For most practical purposes this is quite unimportant.

Duxochrome. This is a pigment process like carbro, but the image is obtained by direct development. It uses special films consisting of a gelatin layer containing both sensitive silver salts and colour pigment mixed together and coated on a celluloid base. Three separate films are provided, one for each colour. After exposure to the appropriate separation negatives the films are developed in a tanning developer and the surplus gelatin washed off in hot water. Since the Duxochrome film con-

DYE TRANSFER IMAGE FORMATION. 1. Latent image formed on inside of emulsion layer of matrix film exposed through base 2. Silver image developed in tanning developer. 3. Gelatin relief left after bleaching of silver and treatment in hot water. 4. Dyed gelatin relief brought into contact with gelatin coated and mordanted paper. 5. Dye image transferred to gelatin layer of coated paper after removal of matrix.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

tained coloured pigments the resulting relief images have varying depths of gelatin mixed with proportionate amounts of pigment and developed silver.

To complete the print the silver image is removed by bleaching and fixing and the reliefs are transferred and registered in turn from their celluloid supports on to a final gelatin-coated paper.

Dye Transfer. Three separation negatives are made from the original subject or transparency, using suitable blue, green and red filters. These three negatives are printed on to special matrix films which are developed in a tanning developer. The silver is bleached out and the untanned gelatin is then washed away by means of hot water.

The matrix from the red separation negative is placed in a bath containing cyan dye, which it absorbs in proportion to the amount of gelatin present in the matrix. The matrix is then washed and placed in contact with a specially-prepared (pre-modulated) paper which absorbs the dye from it.

The procedure is then repeated with the other two prints, using a magenta dye for the matrix made from the green separation negative and a yellow dye for the matrix made from the blue separation negative.

Once a satisfactory print has been made the same matrices can be re-dyed and used for making inexpensive duplicate prints at the rate of one in 15 to 30 minutes.

Chemical and Dye Toning Processes. With these processes the three separation positives are coloured by toning or dying and are usually made on stripping film. This type of film allows the gelatin images to remain on a support until they are ready to be superimposed to form the final colour print. Compared with dye transfer there is the disadvantage that a new set of reliefs are needed for each subsequent print.

In the chemical toning processes the images are first bleached then toned in solutions which convert the silver images into metal ferrocyanides, such as nickel, lead, cadmium, iron, etc.

Finally the silver ferrocyanide is removed with hypo leaving the metallic images ready for combining.

In dye toning processes the image is bleached in a mordanting bleacher which selectively mordants the gelatin. On immersing in a suitable dye solution, the gelatin layer absorbs the dyes in proportion to the densities of the original image, producing a dye image. Three appropriate dye images are then combined in the print. H. (J.M.W.)

COLOUR SENSITIVITY. Relative response to light of an emulsion over the range of wavelengths included in the spectrum. In addition to the visible spectrum, most emulsions are partly sensitive to ultra-violet rays. Some have special responses (e.g. to infra-red).

See also: *Negative materials; Sensitizer; Spectral sensitivity; Spectrography.*

COLOUR SENSITOMETRY

The general principles of colour sensitometry are similar to those of black-and-white sensitometry. The procedure involves making a controlled series of exposures at different levels of illumination on the test material, and, after processing, examining the image with a suitable instrument, usually a densitometer. However, in the case of colour materials there are three emulsion layers, each of which must receive the correct exposure, and then be measured. Further complications arise from the relationship between the three layers and from many effects which on a single film would have little significance but require accurate testing and measurement when dealing with colour materials.

Nowadays virtually all colour films work on the subtractive principle, using three overlapping dye images that produce the appropriate colour by subtracting from white light suitable proportions of red, green or blue light with additive colour materials and separation negatives the individual images do not overlap, and therefore need not absorb only one primary colour. In fact they are usually formed of silver. However, the sensitometric considerations are much the same, and in the following sections it is assumed that the test materials are of the subtractive type.

SENSITOMETERS

A typical colour sensitometer exposes the film in contact with a density wedge to the light from a standard lamp. The shutter system consists of a sector wheel and a capping shutter. The sector wheel rotates continuously at a fixed speed, and the capping shutter remains open while the whole area of film is exposed just once. The exposure time is controlled by the speed of rotation of the wheel and the angle of the sector. Some sort of filter is usually included in the optical path to modify the colour

COLOUR FILM EXPOSURE. Simple representation of the build-up of the three dye layers in a colour negative film. Actually the images do not develop from the bottom of the layer upwards but are distributed more uniformly. B–Y, blue sensitive, yellow-forming layer. G–M, green sensitive magenta-forming layer. R–C, red sensitive cyan-forming layer. f, yellow filter layer.

of the light. Each component requires special attention, and these are described below.

Light Source. This must provide light similar in quality to that which the film will receive in normal use, so that the sensitometer correctly measures the relative speeds of the three emulsion layers. The most commonly used source is a tungsten projection lamp operating at a colour temperature of about 2,800 to 3,100° K. The use of tungsten lamps has several advantages: they emit a continuous spectrum and the colour temperature of the lamps can be adjusted with the applied voltage. Furthermore they are readily obtained and replaced. For simulating daylight a blue correction filter must be included with the lamp.

Although the light distribution made up from sunlight and skylight does not match that from a black body at any colour temperature, a near approximation is between 5,000 and 6,000° K., obtained with a tungsten lamp and a suitable conversion filter. Thus the effective colour temperature of the lamp can be chosen independently, and is usually made as high as possible, consistent with adequate lamp life, to ensure maximum light output.

SIMPLE COLOUR SENSITOMETER. Light from a lamp passes through a shutter for a known time and reaches the film through a wedge in contact with it. The shutter consists of a rotating sector wheel and a capping shutter. A, lamp. B, capping shutter, shown below in open (dotted) and closed positions. C, filter to modify the colour of the light. D, sector wheel. E, wedge. F, film. G, pressure plate.

The original Davis and Gibson filters designed to simulate daylight exactly with a tungsten source, give a better match than glass or gelatin filters, but are inconvenient to use, and not even necessary. For the spectral composition of daylight varies considerably from place to place and with the weather conditions. It is therefore possible only to strike at an average and balance the relative speeds of the three layers of the film to suit this, knowing that the film will rarely receive light made up in just this way. Also, camera lenses all absorb a certain proportion of the ultra-violet radiation, but the exact amount depends on the camera and it is necessary to choose some average amount to adopt for the sensitometer. Even, the exposing wedge absorbs selectively (see below). It is of primary importance that the *total* amounts of light received by each layer of the film in the sensitometer are in the same proportion as in the average conditions of use, and the light distribution at each wavelength should be made as close as possible to that of the average source. Some materials, e.g. colour papers, "positive" film for cinema release prints, and artificial light films, can be exposed directly to the tungsten lamp, or through a filter converting the colour temperature to 3,200° K.

The candle power and colour temperature of the exposing source should be known, and held constant throughout the life of the lamp. This can be corrected by changing the lamp voltage, and the standard distance between the lamp and the film.

Alternative light sources suitable for sensitometry are a xenon arc, xenon flash tube or a mercury vapour lamp, if the specialized nature of the material requires that it is used with these sources.

Exposure Time. It is now generally accepted that practically all photographic materials should be tested by varying the intensity of the light while the exposure time is constant. The effects of reciprocity failure (i.e. the change of speed and contrast with exposure time) are particularly noticeable on colour films because each emulsion layer will behave differently, and a film that is in correct speed and contrast balance at one exposure time will not be so for another. Therefore the exposure time given in the sensitometer must be the same as that normally given. For daylight type colour films 1/25 or 1/50 second represents a good average, while for sheet film used in the studio one or two seconds is probably more appropriate, and an even longer time would usually apply to colour enlarging papers. On the other hand an exposure time of the order of 1/1,000 second is used to show the response of a film to an electronic flash exposure.

Exposing Wedge. Whether a wedge provides a continuous variation in density or is divided

into steps depends on the measuring device. Automatic recording densitometers will generally work with samples that have received a gradual change of exposure with distance along the film, whereas densitometers that give a single reading from a piece of film will require the use of a step wedge. The latter is much more common, since the densitometers are less expensive, and the results from a stepped exposure are more easily assessed visually. For colour materials the density increment for a continuous wedge should not be more than 0·3 per cm. and for a step wedge the density difference between steps should not be more than 0·30 (laid down by American Standard ASA.PH. 2.21, 1961, and the British B.S. No. 1380, 1962).

Most important, a wedge should absorb equally at all wavelengths. The materials usually used as absorbing media are a suspension of carbon in gelatin, which absorbs more in the ultra-violet region and less in the infra-red than in the visible spectrum, and silver chemically developed from silver halide. Silver also tends to absorb less in the far red and near infra-red regions, but it is possible to modify the colour with additives to the developer.

The importance of exact neutrality can be gauged from the following rough calculation. Suppose a continuous wedge 15 cm. long with a gradient of 0·3 per cm. has a density in the red region 1 per cent less than that in the blue. At the dense end of the wedge, with a density of 4·5 the discrepancy has produced a density difference of 0·045, for the two parts of the spectrum. A density difference of 0·045 is equivalent to a difference in transmission of 11 per cent. Thus the quality of light reaching the film is quite different from that leaving the source and correction filter, and foils any attempts to make the source exactly resemble, say, daylight. In fact the correction filter should really be designed to produce the right result in conjunction with the central portion of the wedge, because it is here that the middle densities in the film will be produced—these are the most important for judging colour balance.

Because of the inherent difficulties in making good wedges alternative methods have been tried for varying the exposure, e.g. moving the film past an illuminated slit, while the aperture of the optical system is changed.

Standardization. As in the case of black-and-white sensitometry, careful control is essential at every stage of the testing procedure. The exposure time, the colour of the light and the level of illumination in the sensitometer must be specified. Also, the materials must be used in the correct safelight, the duration between exposure and development must be held constant, and the film storage and processing must be carried out in standard conditions. The errors likely to arise from carelessness in any of these matters are very much more complicated than in the case of black-and-white sensitometry.

DENSITOMETRY

Since it is the task of a colour film to separate the light into red, green and blue components, and then to form the final image by modifying the proportions of these colours, it is reasonable to analyse the result by measuring the densities through red, green and blue filters. Transparencies, colour cine films and prints are finished products, to be looked at directly, and it might be considered appropriate to use colour filters whose spectral transmissions resemble the three (hypothetical) light sensitive components in the eye. Although many instruments for measuring colour do in fact use filters of this type, they are not suitable for colour densitometry. Apart from reproducing colours, the first and most important task of a colour film is to reproduce correctly a neutral grey (i.e. a non-selective absorber). When formulating a colour film from its component layers we must

VISUAL SENSITIVITY AND FILTER TRANSMISSIONS. Top: *Variation of sensitivity with wavelengths for the components of the eye. The curves approximate to those defined for the standard observer by the C.I.E.* Bottom: *Transmission characteristics of three filters used for colour densitometry. These curves have been drawn to a peak transmission value of 100 per cent. In practice even the maximum transmission of a narrow cutting filter might be as low as 25 per cent.* B, G, R, = *blue, green, red.*

know how much of each dye is necessary to make up a visually neutral image. Therefore the densities obtained from single dye layers should in some way indicate what contribution they will make to the final image.

This is not the case if wide band filters are used because successive dye densities effectively shift the absorption maximum away from the peak transmission of the filter and the dye densities are then no longer additive. Only if measurements are made at a single wavelength would the combined density of several layers be the simple algebraic sum of their individual densities. In practice therefore, narrow-cutting filters are used, transmitting narrow bands of the spectrum centred at about 430, 530 and 630 mμ. The exact choice of filters depends on the type of material, and to some extent on the densitometer. An infra-red absorbing filter must be included in the light beam, as most colour filters and all film dyes transmit quite freely in this region, and any residual infra-red radiation in the system leads to underestimation of densities, particularly at high values. Photocells and photomultipliers vary greatly in their sensitivity to infra-red radiation. It is necessary to choose a cell with high red sensitivity, so that high densities can be measured in this colour; at the same time the high *infra*-red sensitivity associated with this calls for a strong I.R. absorbing filter.

For the measurement of colour negative films, the problem is more straightforward. The effective density of each sample depends on the colour sensitivities of the colour paper or positive film). Therefore the spectral transmissions of the filters (taken in conjunction with the emission of the lamp in the densitometer, and the sensitivity of the photocell or photomultiplier) should match the spectral sensitivity of the paper. The instrument will then record the true printing densities of the samples, and any effects due to the densities of single dyes not indicating their contribution in the presence of the other dyes is the same for the densitometer and the paper. (In fact filters matching paper sensitivities are also very narrow cutting.)

Types of Densitometer. There are two main types of densitometer. In the first the light reaches the photocell after passing through the colour filters and the sample. The signal is amplified and the reading of density is recorded on a meter, usually in such a way that the meter reading is linear with density. If a photomultiplier is used as the receiver the amplifying circuit can be designed to give a current output that is approximately linear with density. The instrument can be set to read zero when no sample is in the light beam either by adjusting the lamp brightness (this will change the colour slightly, but if the filter is very narrow cutting, it will have no effect on the result), inserting an optical wedge in the beam, or by a compensating device in the electrical circuit. Some refinements that can be made to this type of instrument are a servo mechanism to record the density on a chart (in effect to draw a characteristic curve for each dye image) and a tuned amplifier—ensuring a minimum of interference from outside sources.

In the second type of optical system the light, after passing through the filters can be directed to the photocell either via the specimen and a compensating wedge, or via a fixed or "zeroing" wedge. The principle is that the light intensity in the two light paths should be the same, and the meter is used simply as a null detector. The instrument is first set by moving the wedge in the reference beam until the light intensities are equal. When a sample is inserted the compensating wedge is moved until the combined density in the specimen beam is back to the original value.

The movement of the wedge can be recorded on a scale, which can be calibrated in terms of density once the density increment of the compensating wedge is known.

Again, refinements to this type of instrument are possible.

The light beam can, for instance, be diverted alternately through each path at a high frequency, the amplifier being tuned to this frequency, and a servo mechanism can be made to drive the wedge, attached directly to a recording pen, until the balance point is reached automatically.

BASIC OPTICAL COMPONENTS OF DENSITOMETERS. Top: *Here the characteristics of the amplifying circuit are designed to give a reading in terms of density.* Bottom: *In this system the results are based upon the calibration of the measuring wedge. Both types have advantages and disadvantages and both are extensively used.* A, *lamp.* B, *infra-red filter.* C, *colour filter.* D, *film.* E, *opal diffuser.* F, *photo-cell.* G, *amplifier.* H, *meter.* J, *chopper splitting the beam from the lamp into the specimen beam (dotted) and a reference beam (dashes).* K, *fully reflecting mirrors.* L, *calibrating wedge.* M, *measuring wedge moved across the light beam.* N, *density scale. The optical systems also contain certain subsidiary lenses and mirrors.*

As a modification, the instrument can be made to read zero for each colour separately without moving the reference wedge either by inserting pale coloured filters into the reference beam, or by a suitable circuit in the amplifier.

In each optical system an opal diffuser is placed immediately below the sample to ensure that the diffuse density is measured. As in the the case of black-and-white material, all standard specifications are made on the basis of diffuse densities. (The difference between specular and diffuse densities is not very great for dye images which do not scatter light to the same extent as silver.) Measurements of reflection density are also made to the same standard as for black-and-white papers; the paper is illuminated at an angle of 45° + 5° to the normal and the light reflected in a cone 5° around the normal is measured (or vice versa). Both types of densitometer can be used for reflection measurements.

Correction of Density Scale. As already shown the most important type of image to be measured on a colour film is a visual neutral. It is preferable therefore that a densitometer can indicate a visual neutral image by recording exactly equal densities in each colour. This will not necessarily happen, because the image is made up from selectively absorbing dyes, and the resulting combination may not absorb equally at all wavelengths. If narrow-cut filters are used to measure the densities the results in each colour will be slightly different. Although another set of filters may give equal densities, the choice of filters is limited. The minimum densities must not be too high or the instrument may have insufficient sensitivity, and the filters must be readily obtainable and stable to prolonged exposure to light.

Therefore an alternative method of ensuring the right result is to alter the density scale so that each colour has its own calibration. In the first type of instrument this can be carried out in the electrical circuit of the amplifier, and in

NEUTRAL IMAGE CURVES. Top: *Spectral absorption curve of a visually neutral image on reversal film, with the central regions of the transmission band of densitometric blue, green and red filters. These filters would not give equal densities in each case.* Bottom: *Absorption curves of the three dyes (yellow, magenta, cyan) that combine to form this visually neutral image. The curve CF represents uncoupled colour former and any residual image colour not due to the three basic dyes. The densities of the dyes taken singly vary greatly according to the wavelengh of light used for measurement.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

the second case the connection between the compensating wedge movement and the pen movement can be made via some sort of variable gear (which can be electrical in nature). This type of correction is a feature of only the more elaborate instruments. The original settings must be made with sample whose densities have been found by independent means. This involves making visual measurements of density and colour, using an optical system whereby the inverse square law of intensity distribution is used as the initial reference. This type of correction can also be applied to the measurement of colour negative films if the filters do not quite match the emulsion sensitivities of the paper. Again the densities of several samples must be found by experiment to supply the initial settings.

INTERPRETATION OF RESULTS

It is possible here to give only a brief indication of the various factors in the reproduction of colours by films.

Reversal Films. The significant factors in the characteristic curves of a reversal film are the shoulder speed of each layer (i.e. the point where the density first begins to decrease with increasing exposure), the contrast and shape of each curve—particularly in the lower densities, and the minimum density of each image. If the measurements are made with an instrument with corrected density scales, the three curves should be superimposed. If the maximum densities are sufficiently high (above about 2·7) they need not be equal. Typical faults are lower speed of one sensitive layer, giving a complementary bias in pictures, and a low maximum density of one of the dye images. If the contrast of the three images is not matched the transparency will have different colour casts in highlights and shadows.

Negative-Positive Material. In a negative colour film the exact speed balance between the layers is not so important, although the absolute speeds (where the density first begins to rise with increasing exposure) of course, should be sufficient for the purpose, and the minimum densities of the three images can be higher than for a reversal film. Both these factors can be taken care of at the printing stage. On the other hand the curves should all include a long straight line portion, and should all be of exactly equal contrast. For example, if the contrast of the cyan image is too low; this would give rise to cyan highlights and red shadows in the prints.

Colour paper is also a "negative" material, but since it is used with negative film the final image is positive, and must have characteristics similar to that on a reversal film. Therefore the important features of a colour paper are a very low minimum density in each colour; each layer must have the same contrast (at the required value) and the maximum densities must be

CHARACTERISTIC CURVES OF COLOUR MATERIALS. Top: *A reversal colour film, exposed to light of the same colour as used for camera exposures.* B, R, G, *indicate the three sensitive layers;* S, *is the shoulder speed for each layer. This curve family shows too slow a blue sensitive layer (leading to a yellow cast in the film) and too low a maximum magenta density.* Centre: *A colour negative film. The red curve is noticeably shallower than the other two, leading to too low a cyan contrast in the film (too much cyan in the highlights and too little—i.e. too much red—in the shadows).* Bottom: *A colour paper. The colour of the exposing light, though similar to that in a colour print, has been carefully adjusted with colour correction filters so that the image on the paper is close to neutral. These curves show a high fog level in the yellow-forming (blue sensitive) layer leading to yellow highlight stains. The contrast and maximum density of the magenta image (due to the green sensitive layer) are lower than for the other two images—a fault in this particular paper sample shown up by the characteristic curves.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

sufficiently high—this is about 2·5 for a colour paper.

The requirements for a colour positive film are similar to those for a paper, except that the maximum densities will be higher as it is a transparent material.

Colour Wedge Exposures. Colour sensitometry must include wedge exposures made through colour filters, in addition to white light exposures. The fact that three dyes happen to be present in just the right quantities to produce a neutral image conveys nothing about the individual dyes. For example, if a magenta dye was particularly poor and absorbed heavily in the blue region, very little yellow dye would be needed in the neutral image. Thus yellows would tend to be washed out, and greens (containing cyan and yellow dyes) would contain too little yellow dye, and would appear bluish. These faults can only be detected from coloured exposures, and may need advanced colour correction.

Other examples of the type of information can be obtained from coloured exposures are: the minimum red density of a saturated red which contains the maximum quantities of magenta and yellow dyes, the change of blue density with increasing green exposure—indicating the purity of the magenta dye, or, in the case of a masked material, the masking efficiency, and the apparent speed to blue light of the green sensitive layer—indicating the efficiency of the yellow filter layer. M.G.F.

Books: *Sensitometry*, by M. Dubois and L. Lobel (London); *Principles of Colour Photography*, by R. M. Evans, W. T. Hanson and W. L. Brewer (London and (New York); *General Sensitometry*, by Yu. N. Gorokhovskii and T. M. Levenberg (London).

COLOUR SYNTHESIS. Any colour of the spectrum can be perceived by the agency of one or more of the systems of receptors forming the retina of the eye. Colours intermediate between any two of the primary colours blue, green, and red, act on two systems. White light affects all three systems equally. So white light, or any chosen colour, can be reproduced from the raw material of the three primary colours, blue, green, and red. This fact is the foundation of every system of colour photography in use today.

There are, however, two different ways of arriving at any particular colour: additive and subtractive synthesis. In additive synthesis, the colour, say yellow, is produced by adding together green and red light. In subtractive synthesis the colour is produced by subtracting colours from white light; in this case blue is subtracted, leaving yellow.

Additive Synthesis. The general principles of additive synthesis can be best understood by following what happens when the process is used to make a coloured photograph of a typical subject like a bunch of red, yellow, and blue flowers and green leaves against a white background.

The first step is to take three photographs on panchromatic material through three filters, red, green and blue. The filters used are called tricolour filters because each is transparent to roughly one-third of the spectrum, just as three sets of receptors in the eye are each believed to be sensitive to one-third of the spectrum.

(1) The red filter passes the red light from the red flowers, and most of the yellow light from the yellow ones. All the light passed by this filter affects the emulsion and produces a black deposit on development. But the green and blue light does not get past the filter and does not register on the plate. So the green and blue areas will remain clear on the negative when it is developed. The negative is now used to make a positive transparency on a lantern slide. The clear areas on the negative corresponding to the image of the leaves and the blue flowers reproduce as black areas on the positive.

(2) The green filter lets through the light reflected by the yellow flowers and green leaves, but stops that from the red and blue flowers. So a positive transparency from this negative will show the red and blue flowers as a blackened image while all yellow and green areas will be clear.

(3) The blue filter only lets through light from the blue flowers so its transparency will show the red and yellow flowers and the leaves as dark areas, and the blue as clear patches.

Now all three positive transparencies are projected from three lanterns on to a screen, one on top of the other, each through the filter it was taken with. The background will be clear on all slides and "add up" to white. But on two of the slides (the green and blue), the image of the red flowers consists of an opaque deposit of silver which prevents light getting to the screen. So only the light from the red lantern gets to the screen. This gives a red image of the red flowers.

The image of green leaves exists as opaque silver on the red and blue slides, so the only light that can reach the screen through the leaf image comes from the green lantern, giving a green picture of the leaves.

In the same way the blue lantern projects a picture of the blue flowers which are blocked out in metallic silver on the slides in the red and green lanterns.

The image of the yellow flowers only appears as an opaque deposit on the slide in the blue lantern, so that it allows both red and green light to shine on the screen. These two colours appear to the eye as yellow, so the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

whole picture is reproduced in its proper colours. The process is an additive process, because it arrives at the result by adding the three different pictures from three separate lanterns.

At the same time, however, each filter cuts out at least two-thirds of the white light available and uses only one-third at best.

Additive synthesis as here described formed the basis of the first demonstration of colour synthesis in photography. It has, however, never been used to any extent in practical photography. All additive systems of colour photography depend on splitting up the image into microscopic red, green and blue elements placed side by side. Owing to their small size, the elements are fused by the eye and produce the same effect as the three superimposed lantern slide images.

Subtractive Synthesis. The second system of synthesis works in a different way. It is concerned not with the colour of light that a filter will pass, but with the colours it holds back. From what has been said, it is clear that a filter is transparent (or nearly so) to one set of wavelengths, and nearly opaque to the others. So when a filter appears a blue-green colour, it is because it lets blue and green light through, but stops red light. It is, in fact, subtracting the red light from the white light shining on it. So a blue-green (or cyan) coloured filter can be regarded as a "minus-red" filter.

A filter that looks a magenta colour because it subtracts green rays from the white light shining on it is a "minus-green" filter.

A yellow filter—one that subtracts blue rays and passes green and red—is a "minus-blue" filter.

These "minus" filters are the key to the subtractive processes. The following illustration gives the general principles on which all such processes depend:—

As in the previous example, the subject may be a bunch of blue, red, and yellow flowers, and green leaves, against a white background. As before, three negatives are made through filters of the primary colours, red, green and blue, and these three negatives are used to make three corresponding positive transparencies.

At this point, the black areas of developed-out silver are treated with chemicals and transformed into corresponding areas of transparent colour of the minus or complementary colour of the filter through which they were taken.

To take them in order: the positive from the red filter is converted into a minus-red or cyan (blue-green) colour; the positive from the green filter is converted to a minus-green or magenta colour, and that from the blue filter into a minus-blue or yellow.

Now, instead of being projected separately, the three transparencies are bound together in register and projected as a single slide. Since the background on all three positives, the background will be white, the colour of the projection light.

(1) The red flowers are registered on the green and blue filter positives, which are now minus green and minus blue in colour respectively, that is they subtract the green and blue light from the white light in the lantern, and so leave only red, the correct colour.

(2) The blue flowers which registered on the red and green positives are now represented by minus-red and minus-green areas—i.e., areas which, correctly, allow only blue light to pass to the screen.

(3) The green leaves which registered on the red and blue positives are now represented by minus red and minus blue areas—i.e., areas which, correctly, allow only green light to pass through.

(4) The yellow flowers only leave a positive image on the blue filter positive. This image is now represented by minus blue which is, correctly, yellow.

So the final result is a picture in the natural colours of the original subject.

Subtractive Analysis. The subtractive system described above still analyses the colours by utilizing red, green, and blue taking filters. In a multi-layer subtractive system the colours are similarly analysed by having three emulsion layers, sensitive to blue, green, and red respectively, superimposed during exposure. The three layers are then processed simultaneously to produce the colour images in the complementary minus colours and yield either a colour transparency or—by interrupting the process at an intermediate stage—a colour negative.

The latter then yields a colour positive by repeating the steps of subtractive analysis and synthesis.

These systems are the basis of most present-day colour materials.

Dyes v. Pigments. In general, colours in the form of pigments are not as brilliant as those of the spectrum. This is because they do not have a very sharp break between the colours they absorb and those they reflect, but tend to absorb all wavelengths of light to some degree although reflecting some more strongly than others.

So pigments are not really ideal for photographic colour processes although they are still employed.

The modern synthetic dyes are usually more brilliant and are almost universally used in present-day colour processes. Some of the subtractive processes, in fact, depend upon the synthesis of the dye while development is proceeding. J.Mo.

COLOUR TECHNIQUE

In colour photography, pictorial effects depend on colour differences rather than contrast of tones as in black-and-white work. Quite small colour differences will show up much more than similar tone differences in monochrome.

The Effect of Colour. The way of using colour depends to a great extent on personal taste. Some colour combinations are, however, generally accepted as harmonizing and others as clashing. The way in which they are combined emphasizes or subdues different parts of the scene. If there is too much colour in a colour picture, all the shades will compete with each other or even clash. It is better to include only one or two brilliant patches of colour at a time. A brightly coloured costume, for instance, may show up the ability of the film to record the colours, but will distract attention from everything else in the picture. On the other hand a small red scarf may add to the character and charm of the wearer.

It is also wise to avoid many splashes of colour in the background or away from the centre of interest. Use colour to help to knit the picture together—not to pull it apart. Brightly coloured areas near the edge of the frame tend to lead the eye out of the picture.

Colours can differ in various ways. Firstly, they may be pure or impure. Pure colours are more likely to clash than impure ones. Secondly, colour schemes can be built up on similar or contrasting colours. Similar colours may blend while contrasting colours set each other off.

By association of ideas, colour may also create an atmosphere or a mood.

COLOUR BALANCE. Centre: *The colours of the colour wheel are G, green; Y, yellow;* O-R *orange-red;* B-R, *blue-red (magenta);* V-B, *violet-blue,* B-G, *blue-green.* Top: *Adjacent segments indicate harmonizing colours (shaded).* Bottom: *Opposing segments (solid) are contrasting colours.*

Colour Harmony. In harmonizing different colours, the hue as well as the saturation is important. The more saturated the colour, the more brilliant it appears. Mixing with white de-saturates it, dilution with black degrades it. Thus a mahogany brown, a bright red, and a pale pink may all be the same hue; but the brown is degraded, the red fully saturated and the pink desaturated. Colours of the same family or hue but of different saturation will easily blend and harmonize.

Colour Contrast. The contrast between different colours is greatest when they are complementary (blue and yellow, red and blue-green etc.).

Two fully saturated colours of equal area will conflict with each other and fight for attention. This disharmony is greatest when colours are not complementary; thus a pillar-box red and a magenta or a blue and a blue-green, will clash.

A bright colour against a desaturated complementary will appear brighter than against a saturated non-complementary. This use of complementary colours helps to focus the eye on the subject.

Colour and Warmth. Certain colours—e.g., yellows and reds—suggest warmth: others—e.g., blues and greens—suggest coldness. Cool colours also appear to recede and warm colours to advance. This is partly due to the fact that the eye focuses reds and yellows as if they were nearer than blues and greens. Similarly, light and desaturated tones in a picture tend to seem more distant than darker and more brilliant tones. This again is based on experience—e.g., of the way in which the planes of a landscape become paler as they recede into the distance.

These factors are able to create depth. Thus yellow and reddish colours (including brown) in the foreground make it stand out, while greens and blues in the background make it appear farther away.

Colour and Sharpness. Brilliantly coloured objects in the picture should be sharpest; shapeless blobs of saturated colours are most disturbing. Subdued and pastel shades can be less sharp; the subject should be selected so that the background colours are more subdued than those of the principal subject. When photographing a scene which takes in foreground, middle distance and background alike, everything must be sharp. The depth of field requirements in colour are therefore more stringent than in black-and-white photography.

Equipment for Colour. Practically any camera can be used for colour shots provided the light is good enough, but the scope of simple

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

cameras is very limited because such a camera does not provide sufficient adjustment of lens aperture and shutter speed to cope with more than a very restricted range of light conditions. The shutter speed or speeds on a cheap camera are often not as reliable as they should be. An accurate shutter is a help in assuring correct exposures, as the latitude of colour film is slight. For large scale colour photography the camera lens should be well corrected for all chromatic faults It should also be coated, since stray light caused by reflections inside the lens and scattered over the film will desaturate the tones. For the same reason it is always wise to use a lens hood.

Loading of colour film into the camera follows standard practice. It is, however, advisable to cover the red film window at the back of many roll film cameras at all times, except when actually winding on the film, to avoid the risk of fogging.

It is, of course, possible to take colour photographs without using colour film. The method involves taking three black-and-white photographs of the subject, separately, through red, green and blue filters. This is nowadays used mostly for photomechanical reproduction and the negatives are known as colour separation negatives. Such negatives of moving subjects can be taken only with a one-shot colour camera taking all three pictures at once each through its correct filter. These cameras are nowadays obsolete. The separation negatives are used to make a colour print by superimposition of complementary coloured positive images.

The Colour of the Light. Since colour film records all variations in hue and tone, it will also react to the different colours of light sources by which the picture may be taken. That is why reversal colour materials are specially balanced for use in either daylight or artificial light. Within both types of lighting, however, there are variations in colour quality depending on specific conditions.

Three main factors affect the colour of daylight.

(1) Atmospheric dust filters the sun's rays, and absorbs or scatters rays of short wavelength (violets and blues) more than those of longer wave-length (reds and yellows). When the sun is low on the horizon the light becomes redder; on the other hand, just before sunrise or just after sunset the colour will sometimes be blue due to reflections from a clear blue sky. Except for special effects it is therefore best to avoid taking colour pictures within approximately one hour after sunrise and one hour before sunset.

(2) Over water, snow, or from distant views a great deal of ultra-violet radiation may reach the camera. Although this is invisible to the human eye, the colour film is sensitive to it and the resulting picture may be too blue. (In addition many lenses are not corrected for ultra-violet radiation, and such rays may therefore upset the definition of the image on the film.)

THE COLOUR OF DAYLIGHT. Top left: *Brilliant sun with a cloudless sky produces intensely blue shadows. Subjects in shadow require a correction filter.* Top right: *White clouds lighten shadows, and make them less blue.* Bottom left: *Low evening sun is yellowish, while the shadows are again blue. The yellow tinge can be corrected by a pale bluish filter.* Bottom right: *Overcast days yield a flat and cold colour rendering, requiring a pale correction filter.*

(3) Part of the light reaching the earth does not come directly from the sun but is reflected from the blue sky. When the sun is shining in a clear sky the shadow parts of the subject may be lit only by the sky and therefore tend to take on a blue tint. Colour film tends to overemphasize this. Conditions for colour photography are generally best when there is a lot of white cloud about; this lights up the shadows and also makes them less blue. In overcast weather the colour of the diffused daylight is also bluer than direct sunlight, but not so blue as the light from the clear sky.

The colour temperature of most artificial light sources (with the possible exception of electronic flash) is lower than that of daylight, and will record a yellowish or reddish over-all cast on daylight type colour film. Artificial light type films are made more sensitive to blue to compensate for the excess of red in the light.

Most amateur artificial light type films are balanced for Photoflood lamps and are ideal for colour photography at home. A few makes are balanced for high-power studio lamps of slightly lower temperature and others for clear flash bulbs. Ordinary flash is yellower than daylight. So flash bulbs for colour photography are tinted blue, to match daylight.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Fluorescent tubes of the "colour matching" type are similar to actual daylight; white tubes are a little yellower, but give a reasonable colour rendering on daylight film. Special colours like warm white, pink, etc., may distort the colours of objects and are less suitable for normal colour photography.

Filters and Colour Balance. Correction filters may be required to adjust the colour balance of the film to suit the lighting. This applies especially to reversal colour films where there is no intermediate stage of colour control as there is with negative films.

In general, extreme correction measures are only advisable in an emergency. Apart from the fact that the results are inferior to those obtained when using the proper film-light combination, the filters also require appreciable exposure increases. This is specially so with the conversion filter for daylight film used in artificial light.

Exposure. Under- or over-exposure with colour film upsets the colour rendering as well as the subject tones.

Slight over-exposure makes flesh colours pale, and slight under-exposure makes them richer. Darker colours become washed out by over-exposure, and are degraded by under-exposure. But if the subject contains few dark areas, slight under-exposure may actually improve the rendering of flesh tones.

Colour films are particularly liable to reciprocity failure—the loss of speed (and often also change in colour balance) at long or very short exposure times. Preferably adjust the lighting on the subject (or choose subject conditions) to permit exposure times not longer than about 1/10 or 1/5 second. With subjects requiring a longer exposure time (for example artificial light set-ups indoors) the exposure may have to be increased above the calculated exposure for that lighting level.

Special artificial light colour films exist which are designed for long exposure times, between 1/10 and 10 seconds.

The high sensitivity of the colour rendering to differences in exposure level is due to the fact that all three layers of a colour film may have individual reciprocity failure characteristics that can either compensate or reinforce each other. For that reason two makes of colour film of similar speed and colour rendering at normal exposure levels (1/10 second or shorter times) may diverge radically in both speed and colour rendering at long exposure times.

Exposure Charts and Tables. Most colour film packages include exposure tables issued by the manufacturers; these are reasonably accurate for normal daylight (or artificial light) conditions. But to be absolutely sure, it is usually best to take three exposures of the subject, at half a stop below and half a stop above the estimated aperture, in addition to the exposure which has been estimated as "correct".

Most charts or tables advise increased exposures for very dark subjects and decreased exposures for very light subjects. If, however,

CORRECTION FILTERS FOR COLOUR

Subject or Light Cause	*Film*	*Effect*	*Filter required for Correction*
Water, snow, mountains, distant views	Daylight	Blue cast due to ultra-violet radiation	Ultra-violet or pale straw
Distant views with haze	Daylight	Blue cast	Pale straw (haze
Outdoors with overcast sky	Daylight	Bluish, cold colours	Pale straw
Subjects in shadow under blue sky	Daylight	Strong blue cast	Medium straw
Early morning or late afternoon lit by sun	Daylight	Yellowish colours	Pale blue to give mid-day colouring; none to record effect faithfully
Normal daylight	Artificial light (Type A or B)	Strong blue cast	Yellowish to orange conversion (according to film type used). Recommended only in emergencies
Blue flash bulbs electronic flash	Daylight	Correct	None
Clear flash bulbs	Daylight	Yellowish cast	Bluish conversion
	Type A and B	Slight bluish cast	Yellowish light balancing
Indoors with Photofloods	Daylight	Yellowish cast	Blue conversion not recommended except in emergency
	Type A	Correct	None
	Type B	Very slight bluish cast	Very pale yellow light balancing
Indoors with studio lamps	Daylight	Yellow cast	Blue conversion not recommended except in emergency
	Type A	Slight yellow cast	Pale blue or mauve light balancing
	Type B	Correct	None
Indoors with household lamps	Types A and B	Yellow cast	Mauve light balancing
	Daylight	Strong orange cast	Lack of balance too great to be cured successfully by filter

Type A colour film is balanced for 3,400–3,500° Kelvin, Type B for 3,200° Kelvin.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

human faces form an important part of the picture, it is advisable to give the normal exposure; this may render dark clothes too dark, but it is preferable to false rendering of the skin tone.

Using Exposure Meters. A meter gives a more reliable indication of the exposure required. Average reflected light readings are sufficiently accurate with evenly lit colour subjects, but close-up individual readings are required if the surroundings are appreciably different from the subject itself in brightness. Highlight readings and incident light measurement are specially suitable for colour exposures, as they tie the exposure to the lightest tones of the scene, where faults in the colours are more noticeable. Specially light or specially dark subjects need some allowance; in the first case use half to one stop smaller, in the second case half to one stop larger.

For portraits the exposure should be based on close-up readings of the skin tone (key-tone readings).

Subject Contrast. Colour films vary in exposure range or latitude. Reversal films in particular tend to be contrasty whereas some negative films more nearly correspond to medium speed black-and-white films.

Therefore, in general, contrasty subjects should be avoided unless it is known from experience that the film can handle them. Even so high contrasts do not usually lead to a satisfying result unless a special effect is aimed at; and if strict colour accuracy is essential this can be guaranteed only in the mid-brightness range, although it depends on the particular colour and therefore the quantities of each dye required to produce it. For this reason it is often stated that the subject brightness range should not exceed 10 : 1, although the film may in fact be capable of recording a 200 : 1 range.

Lighting Outdoors. Direct sunlight produces very strong contrasts and a reflector (e.g., a white sheet, or silver paper mounted on a board, etc.) is advisable to throw light into the dark parts. Sometimes natural reflectors, such as concrete or white sand, will soften the shadows. But coloured reflectors can upset the colouring of the subject—e.g., a brick wall can reflect a rosy tint.

Fill-in flash may be used for brightening up the shadows, particularly in against-the-light shots, which have an extreme contrast range.

The ideal lighting for outdoor colour subjects, especially portraits, is slightly obscured sun, when shadows are only just visible. But colour photographs should not as a rule be made during the midday hours as the light then comes from too high an angle and makes, for instance, the eyes in a portrait appear dark and sunken.

Daylight Indoors. Owing to the strongly directional nature of daylight indoors, reflecting screens or fill-in flash are usually necessary to avoid heavy shadows.

If there is only one window, the subject

OUTDOOR LIGHTING FOR COLOUR. Top: *With subject lit by direct sun and cloud reflections, the colours will be brilliant.* Bottom left: *With direct sun and blue sky, effects are similar but shadows deeper and bluer.* Bottom right: *Front of subject lit by cloud and blue sky makes colours bluish and cold.*

should be as near to it as possible, and neutral reflecting surfaces of silver paper or white card should be used to light up the shadow side. A bay window is ideal as the light then comes from three sides instead of one and, if the room has two windows in adjacent or opposite walls, there may even be no need for reflectors.

Direct sunlight coming in through the window will lead to high contrast and curtains of net or similar diffusing material will have to be used to soften the lighting. This will make longer exposure times necessary.

Artificial Lighting Indoors. Artificial light gives more control of lighting effects and subject brightness range.

There is no great difference between the lighting for black-and-white and for colour, except that the heavy shadows and strong highlights sometimes used for ordinary photography are rarely satisfactory for colour.

All lamps should be fitted with reflectors, preferably painted white inside or with a matt surface to give fairly diffused lighting, free from "hot" spots. Spotlights used for special effects should have the condenser lens of white glass without any trace of green.

All lamps used in a lighting set-up must be of the same colour temperature; this is most easily achieved by having them all of the same kind. Mixing lamps of different types (e.g., Photofloods with ordinary studio lamps) will yield differences in the colour rendering over different parts of the subject. Although the colour temperature of the light itself will affect the colour rendering, an over-all change in colour is not nearly so disturbing as mixed lighting.

The inverse square law has two particular applications to colour photography.

Firstly, when taking head and shoulder portraits only it is possible to increase the level

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

of illumination considerably by putting the lamps close to the head of the subject. But with a half-length or full-length figure the lamp may be nearly twice as far away from the lower part of the subject as from the face. So the head will receive about four times as much light as the feet, and will be over-exposed. The remedy is to move the lamps farther away from the subject or to put additional light on the under-lit part.

Secondly, when the subject is some distance in front of the background and lit by the same light source, the light falling on the background will be only a fraction of that on the subject and the background will thus come out comparatively dark. So if the background is to be reasonably bright it must be separately lighted.

As for black-and-white pictures, a lighting set-up for colour photography consists of main light, fill-in light, effect light, and background light. To start with it is best to use only one or two lamps and aim at obtaining even lighting on the subject; the effect and background lights can then be used to add highlights and contrast where necessary.

For colour subjects the fill-in illumination should only be a little weaker than the principal light and fairly diffused, to avoid creating a second set of shadows. Generally a fill-in lamp very close to the camera lens will achieve the required result. Reflecting screens will also serve for fill-in lighting, if they can be placed close enough to the subject. Yellow tinted flash bulbs can be used as fill-in lighting with Photofloods as the principal light because the colour temperatures are similar.

Flash Indoors. Synchronized flash permits instantaneous exposures, and enables moving subjects to be shot in colour—e.g., children at play, unposed and candid portraits, and people at their normal occupations.

If only one flash bulb is used it is better placed on or near the camera. With a good reflecting screen on the shadow side the flash may be also held to one side of the camera, pointing down at the subject. This increases the lighting contrast, but also improves modelling.

If several bulbs are used, lighting set-ups similar to those with Photoflood or studio lamps are possible with the added advantage of instantaneous exposures. The rules of lighting are much the same in each case.

Flash with Daylight. Blue tinted flash bulbs which match the colour temperature of daylight can be used for fill-in lighting for outdoor or indoor shots by daylight. Electronic flash has approximately the same colour temperature as daylight without any further treatment.

Flash used in this way is a great help when dealing with people who cannot avoid frowning in bright sunshine. It is also invaluable for natural portraits of children, engrossed in play with their heads in full shadow.

When used as a fill-in light the flash must be synchronized with the shutter, since the slowest suitable speeds are at least 1/30 or 1/25 second; open flash technique is rarely possible because this results in too long an exposure to the daylight and the effect of the flash is lost.

The fill-in flash must not be too strong, or its effect will be obvious by the unnatural appearance of the subject, and perhaps by double shadows.

Outdoor flash exposures are calculated in the same way as for black-and-white photography.

A special application of flash outdoors is to give a dark sky background to a portrait or figure. This is done by setting the camera aperture and shutter speed so that the background and subject would by themselves be under-exposed by about 2 stops and then using a flash bulb at the appropriate distance to yield a correctly exposed image. This technique gives a correctly exposed subject and an under-exposed, dark sky background like that produced by a deep filter in black-and-white photography. This is in fact the only way of darkening a sky in a colour picture apart from the use of a polarizing filter.

Outdoor Subjects. Most subjects are better with a simple background like the sky or a subdued area of colour. This is specially desirable with pictures of people, since violent background colours may make flesh tones appear unnaturally pale and lifeless by contrast.

Sunlight with white clouds, or slightly diffused bright daylight is ideal for outdoor colour pictures, since the lighting is then reasonably balanced, even without auxiliary shadow illumination.

Seaside shots on the sands do not usually present great problems; even in bright sunlight the sand acts as a fairly good reflector to light the shadows. If the sand is particularly yellow, it may produce a warm rendering of skin tones due to the reflected light, but this is rarely disturbing. But the tones are apt to be unpleasantly affected if the subject is coloured on one side by light reflected from the blue-sky, and on the other by yellow light reflected by sand.

When the light is as brilliant as at the seaside, it is usually best to arrange for side lighting with a reflector to light the shadow areas. Direct front lighting yields brilliant colours, but colour emulsions (especially reversal) tend to exaggerate the saturation and brilliance of the colours. With the light more to one side, or slightly diffused, the colours are less vivid and correspond more nearly to our visual impression.

Pictures on the water itself, including river and lakeside views, need a haze filter to cut out the ultra-violet radiation reflected by the water. Such views need trees or a human figure in the foreground to impart a sense of distance. The stronger contrast and more vivid colour of the foreground enhances the feeling of depth. Boats make an excellent foreground, with their brightly painted colours and the tones of ropes,

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

nets, etc. Morning or afternoon sun will often produce more brilliant colours here than at midday, because many of the surfaces—boat sides, quay walls, etc.—are vertical and show up best when the sun is low.

Sunlight sparkling on the water is difficult to capture on colour prints but comes out well on reversal film.

Distant landscapes call for brilliant lighting which gives foreground features strong contrast and rich colours, while the distance is weaker and more subdued. The exposure should be based on the foreground objects, leaving the distance to take care of itself.

Woodland scenes with the sunlight streaming through the trees are inviting subjects but the contrast is severe unless they are taken in diffused sunlight.

If the leaves are reasonably transparent, back lighting can provide attractive effects. The exposure should be based on a highlight reading taken with a meter close up to one of the illuminated leaves.

When taking portraits in woods, parks or other green surroundings, it is necessary to watch out for green reflections on faces and clothes.

For mountain shots an ultra-violet or haze filter is almost essential. Both haze and ultra-violet radiation tend to give a blue cast without a filter.

In snow scenes the subject contrast tends to be low, but side lighting from the sun helps to create texture and modelling. The shadows in very clear weather will appear really blue. Exposure should be based on highlight readings.

Sunsets require a suitable foreground to give a base to the picture. As the colours and hues visible vary so much, almost any colour reproduction on the film, provided it is not grotesquely over-coloured, will be acceptable. Exposure readings should be taken with an incident light meter pointed straight at the sky.

Towns and cities are usually less coloured than country scenes, but this fact lends greater value to patches of brilliant colour—e.g., motor cars, summer dresses and blue sky.

In city streets the biggest problem is large areas of shadow and although diffused daylight is best for most subjects, buildings generally look better in bright sunshine. So it is preferable to wait until the sun is out and to choose a viewpoint which reduces the shadow area.

Lighted street scenes in town centres make effective night pictures. Such subjects are best taken on daylight film, as the artificial light type tends to render the lights too blue. The warmer rendering on daylight film is usually more natural and attractive. It is not possible to record the full brightness range of a night scene on the film. On the other hand, the shadows are meant to be completely black, and the amount of black is a matter of taste. So there is a surprising amount of latitude and the results are acceptable over a large range of exposures.

Indoor Subjects. The limited amount of light available indoors usually means that people—singly or in groups—have to be posed in one place. This also allows time to discover unpleasing splashes of colour such as out-of-focus flowers in the background, etc.

Groups in particular must be evenly lighted since complicated lighting schemes may result in disturbing shadows and distorted colour values.

The evenness of the lighting should be checked by taking a highlight reading on a white card at various points in the picture area. The lighting should be adjusted until the highlight readings are constant everywhere.

Walls can be used as reflectors, but only if they are neutral in colour. A flood lamp shining on a white ceiling will provide a diffused general illumination from above.

For portraits a background colour complementary to the subject will provide the best colour contrast. A background in a desaturated hue will brighten the subject colour if it is complementary to it. Flesh tones stand out well against pale blues and greens; but if the background is a warm colour such as cream or yellow, it should be appreciably lighter or darker than the skin tone.

Make-up should be natural and rather subdued, and with sleeveless or topless dresses the photographer should make sure that the skin

LIGHTING FOR COLOUR. **Top:** *A single lamp should be high and to one side, with a reflector for shadows.* **Centre:** *A second lamp (shaded) acts as a fill-in for the main light (solid).* **Bottom:** *Four lamps allow almost unlimited variations, with additional fill-in and effect lighting.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

tone of the arms and shoulders is made up to the same hue as the face. Colour film shows up variations particularly strongly.

Details of skin structure and facial blemishes show up much more plainly on colour film than in black-and-white. For glamour portraits a certain amount of disguising make-up may be necessary or the model should be moved farther away and lighted evenly.

The eyes must be well lit, especially in close-up shots, so that their colour can be seen without being degraded by shadows in the eye sockets. Where face and hands or arms appear in the picture they should be given the same amount of light; under-lighted skin tones not only change in brightness, but also in hue.

Figure studies, and particularly nudes, need carefully chosen backgrounds as well as even lighting. The large area of skin tone present can show appreciable changes in hue if unevenly lit or when near strongly coloured reflecting surfaces. Flesh tones contrast with cool background colours like blue and green and tend to merge with warm tones like yellow or orange. With interiors the greatest danger is an excessive contrast range. Windows should not appear in the picture and exposure meter readings should be made of the brightest parts and the deepest shadows to make sure that they come within the range of the film. Usually several reflecting screens will be necessary to produce more even illumination.

The background will not usually be sharp, but it should still suit the subject. For instance a pale blue-grey background will make yellow flowers stand out well, while dark wood will create a pleasing contrast to pink roses.

A soft but directional light should be used to give good modelling—e.g., a Photoflood with a large diffusing screen. A suitable form of diffused lighting is produced by shining one or more lights on to a large piece of white card and directing the reflected light on to the subject in the manner of a "bounced" flash, so that no direct light falls on the subject. Use a reflector or another diffused lamp to lighten up what shadow there is. G.W. & L.A.M.

COLOUR TEMPERATURE. Measure of the energy distribution over the spectral range (i.e., the colour quality) of a light source with a continuous spectrum provides a fairly easily workable method for comparing and specifying the "whiteness" of illuminants in colour photography.

Kelvin Scale. The colour temperature, expressed in degrees Kelvin (°K.), is the temperature on the absolute scale (°C. + 273) to which a perfect black-body radiator would have to be heated to emit light of the same colour as the light source in question. (A perfect black-body radiator is one which does not reflect any light falling on it.)

Colour temperature measurements are applicable to all solid incandescent light sources such as flash bulbs, filament lamps, etc. (The colour temperature of a filament lamp is for all practical purposes the same as the temperature of the filament.)

SPECTRAL ENERGY AND COLOUR TEMPERATURE. The curves show the relative energy distribution throughout the spectrum (from violet V to red R) of light sources of different colour temperarures. Tungsten lamps (about 3,000° K) are rich in red; balance shifts to blue at higher temperatures.

Precise colour temperatures cannot be stated for discharge lamps as these do not have a truly continuous spectrum. Where colour temperatures of such sources are quoted, they are only approximations.

The lower the colour temperature of a source, the richer the light is in yellow and red rays; the higher the colour temperature, the richer it is in blue rays.

Colour temperature is of special importance in colour photography as colour films are sensitized to give a true colour rendering with light of a specified colour temperature. Thus some films are balanced for a colour temperature of 6,000° K. (daylight), while others are balanced for 3,200–3,400° K. (tungsten or Photoflood light).

The colour temperature of a light source can be modified by special filters which absorb some of the blue or some of the red end of the spectrum. Filters of this type are known as photometric or light balancing filters. For overall correction, they may be used over the camera lens instead.

Mired Values. An alternative way of expressing colour temperatures is the mired (micro-reciprocal degrees) scale. The mired value of a light source is its colour temperature in degrees Kelvin divided into 1,000,000. Thus a colour temperature of 5,000° K. corresponds to 1,000,000/5,000 = 200 mireds, and 3,200° K. to about 313 mireds.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

COLOUR TEMPERATURE. Left: *Typical natural light sources in order of ascending average colour temperature; mean noon sun, average daylight, overcast sky, blue sky.* Right: *Artificial sources are household lamp, Photoflood and other overrun photographic lamps clear flash bulb, blue flash bulb.*

COLOUR TEMPERATURES COMPARED

Type of Light Source	*Approx. Colour Temperature*
Small general service (below 100 watts) ...	2,600° K
Large general service (100 watt and above) ...	2,800° K
Sensitometric lamp (international white light SA)	2,848° K
Projector lamps	3,100° K
Over-run lamps 500 watt (100-hour life)	3,100–3,200° K
Flash bulbs, paste filling	3,300° K
Over-run lamps (275 watt, 2-hour life, and 500 watt, 6-hour life)	3,400° K
Flash bulb lamps, foil or wire filling	4,000° K
Fluorescent daylight tubes	4,800° K*
Fluorescent warm-white tubes	3,700° K*
Electronic speed flash discharge lamps	4,800–6,000° K*
English daylight (international white light SB)	4,800° K*
Mean noon sun	5,000° K*
Blue flash bulbs	6,000° K
American daylight (international white light SC)	6,500° K*
Overcast American daylight (international white light SD)	7,500° K*
North sky, blue	10,000–20,000° K*

American lamps, being run at lower voltage, operate at colour temperatures between 50° and 100° higher than the English lamps here quoted.

*These sources are not temperature sources in the strict sense, and their colour temperature therefore only approximately indicates the quality of light they emit.

The mired values are useful in assessing the effect of light-balancing filters. The degree to which such a filter raises or lowers the colour temperature depends not only on the depth of the filter itself, but also on the initial colour temperature of the source. When the colour temperature is expressed in mireds, the change in the mired value (the mired shift) is more or less independent of the initial colour temperature. Yellowish filters which lower the colour temperature raise the mired value, and have a positive mired shift. Bluish filters which raise the colour temperature lower the mired value and have a negative mired shift.

As a slightly more handy unit decamired values are also used. One decamired = 10 mireds. Light balancing filters are frequently rated in decamired values to indicate their actual correction effect. For example in the reddish series of some manufacturers an R5 filter signifies a decrease of the colour temperature corresponding to raising the mired rating by 5 decamireds.

Special meters, similar in principle to photoelectric exposure meters, are made for measuring colour temperature. L.A.M.

COLOUR TEMPERATURE METER. Instrument for measuring the colour temperature of a light source. It is based on the fact that the spectral-energy distribution of sources at different temperatures can be defined reasonably accurately by stating the relative proportions of red and blue radiation which they emit. An instrument constructed to measure this proportion of red to blue will then give a measure of the colour temperature of any light source.

A typical colour temperature meter consists of a selenium barrier layer type photo-cell connected to a micro-ammeter. Immediately in front of the photo-cell is a circular filter, half red and half blue. These filters are rotated by means of an external lever, and are spring loaded so that the red filter is normally in front of the photo-cell. By pressing the lever, the red filter is replaced by the blue. In front of the filters is a diaphragm which may be rotated to control the amount of light received by the photo-cell.

The instrument is directed towards the light source to be measured and held at eye level. The shutter is adjusted until the pointer of the meter coincides with a red index line on the scale. The filter lever is then depressed, bringing the blue filter in front of the cell in place of the red one. The cell therefore measures the amount of red light and the amount of blue in succession. If the proportion of the two is equal, the meter needle will not move, but if the blue proportion is greater or less, the blue filter reading will be higher or

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

COLOUR TEMPERATURE METER. A, rotating shutter; B, blue/red filter disc; C, photo-cell; D, micro-ammeter.

lower respectively. As the zero setting to the red index also corresponds to a standard colour temperature, the meter reading directly gives the colour temperature of the light source.

Alternative systems may use a null-method with two photo-cells, balancing the red and blue content of the light on them. The drawback of this method is that the response of the two cells may not be the same at varying wavelengths, which would introduce an error.

Visual colour temperature meters rely on matching various shades of fluorescent and non-fluorescent pigments, or on matching the tint of a dichroic filter with a standard tint by means of a filter wedge. This type of meter cannot, of course, give more than a very approximate value.

When the colour temperature measurement has been made it may prove necessary to employ a colour temperature correction filter on the camera.

However, the effects of a correction filter may be assessed by using the meter to measure a light source first without and then with the filter interposed.

Colour temperature meters can also be supplied with a second scale calibrated in mireds ($= 10^6 \times 1/°K$). This scale is of particular assistance when it is desired to select a correction filter, since any true colour temperature correcting filter will give a constant change in mireds irrespective of the source employed. G.C.C.

COLOUR VISION. Ability of the eye to distinguish between radiations of different wavelength within the visible spectral range. In the eye it is the cones (one of the two types of light-sensitive cells or receptors in the retina) which are responsible for the colour sensitivity of the eye. The eye behaves as if it had three types of such receptors, each sensitive to one of the primary colours, blue, green and red. While this theory accounts for a large number of phenomena of colour perception and also provides a working basis for most processes of colour photography, no individual receptors of differential colour sensitivity have ever been found to exist. There are in fact a number of advanced and complex theories of colour vision.

See also: *Colour measurement; Eye; Vision.*

COMA. One of the off-axis aberrations of lenses, resulting in unsymmetrical defects in image points.

See also: *Aberrations of lenses.*

COMBINATION PRINTING. Combination printing and photomontage are used for making pictures from more than one negative or print.

The basic methods are: simultaneous printing of two or more negatives; successive printing; montage.

The first to exhibit photographs combined from several negatives was William Lake Price in 1855. The classic example of this technique is O. G. Rejlander's allegorical composition *The Two Ways of Life*, 1857. It was printed from over thirty separate negatives of single figures, groups, and background. Rejlander's purely photographic technique was to mask all parts of the picture except what was being printed. H. P. Robinson, on the other hand, made scissor and pastepot photomontages which he retouched and rephotographed. His first and best-known composition was *Fading Away* (1858), from five negatives.

A widespread form of combination printing, particularly during the collodion period, was the printing in of separate cloud negatives, first suggested in 1852 by Hippolyte Bayard. Owing to the colour-blind and not very sensitive negative material, the sky became so dense that it printed white if the exposure were correct for the landscape.

Simultaneous Combination Printing. Two (or sometimes more) negatives are placed together, emulsion to emulsion, in the negative carrier of the enlarger, and printed as one. Where parts of the images overlap, they produce lighter tones in the print because the negative densities are added.

The process is often used to reproduce ghost effects and for printing genuine or faked negatives of falling snow, rain, etc., into a picture.

Two identical negatives, or a negative and a positive transparency made from it, can also be combined by simultaneous printing. If one of the two is reversed left to right, a variety of interesting image patterns and shapes is obtainable. The negative and positive used for this method must be relatively thin, because the effective printing densities are added.

Further special effects can be achieved by removing parts of one or both images by local reduction with Farmer's reducer.

The reducer is applied to the emulsion with a plug of cotton wool. If the edges of the reduced area are not to appear sharply defined, the emulsion should first be soaked in water.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

If sharp outlines do not matter, the reducer can be painted on to the dry negative, or the whole negative may be immersed in the reducer after protecting it where necessary with an asphalt varnish, or similar protective lacquer.

Successive Combination Printing. Several negatives may be printed, one after the other, on the same sheet of paper. The appearance of the resulting combination print differs from that obtained by simultaneous combination in that the print tone is darker where parts of the images overlap. For this reason the separate exposures must be reduced, or the print will be too dark. The process can be used for ghost effects in which one image is seen through the other. But as a rule, the separate images are required to merge without overlapping, so a certain amount of complementary shading may be necessary during the separate exposures. This may be done with the hands, or with a suitably shaped card. For complicated combinations specially cut masks and counter masks are used.

This method is used for printing in clouds when the sky in the subject negative is blank. The usual technique is to mount a sheet of thin card on a glass plate supported just above the paper holder on the enlarger baseboard after the image has been focused. On the card the skyline of the picture is sketched in, and the sheet cut along that outline. This yields a mask and counter mask which are realigned in position on the platform. The subject portion is now printed on the enlarging paper with the sky mask in position, the subject mask replaced and sky mask removed, and the clouds exposed finally on the same paper from another negative.

Montage. Different parts of various prints can be cut out and pasted together on a base to make a composite photograph. This is a special and major technique of its own. L.A.M.

COMMERCIAL PHOTOGRAPHY

Commercial photography is the branch of professional photography concerned principally with supplying the need of the sales, advertising and display side of industry, and the art departments of the press and specialized publications.

Nowadays the demand for photographs for all these purposes is so general that there is usually a commercial photographer's business in even the smallest town. The size and scope of the establishment vary widely. In the smaller towns the studio may be a one-man business turning out photographs for local industries and traders. This type of studio may even be run in conjunction with a portrait photographer's business and a photographic dealer's shop. The photographer and his staff in such cases will usually go out to cover weddings, banquets and events of local interest.

In the cities and more particularly in London, the commercial studio tends to specialize almost exclusively on work for reproduction—i.e., on photographs for catalogues, advertisements, posters and sales literature. This type of establishment employs a large staff of photographers, darkroom staff and retouchers. It may even include commercial art and block-making facilities so that the client can be supplied with the finished blocks of the illustrations he has commissioned.

While the large establishments will—and often do—undertake outside assignments they usually prefer to do all the work in the studio where they can keep all the conditions under control and repeat the shot if necessary. Modern trends have encouraged most commercial studios to handle colour; and this in turn has compelled them to adopt precision technique in place of the old rule-of-thumb methods.

The ever widening applications of photography in commerce and advertising are leading more and more studios into specialization—e.g., fashion, advertising, industry, aircraft, architecture. To-day, a studio would need to command a large organization and a team of workers to be able to handle every branch of the work. It would have to be prepared to deal with a wide range of subjects and be ready to apply scientific techniques like industrial radiography, ultra-violet light photography, or ultra-high speed photography, and cinematography. Such work is beyond the scope and equipment of any but the most highly specialized studio.

The word studio is commonly understood to include the whole organization and not merely the room where the photographs are taken.

The Small Studio. The small specialist studio generally adapts itself to the requirements of one class of work. It may, for instance, be designed to handle food pictures for a group of women's magazines. In this case the studio might consist of a room with a cooker in one corner, a typical kitchen table in another, and a plain wall against which small objects can be photographed. For lighting equipment it may manage with a minimum of a couple of flood lights, two focusing spots, and a few portable hand lamps. The camera may be anything from a half-plate to an 8 × 10. As a rule a large size is preferred since retouching can be done on the negative and the prints made by contact. A small room or large cupboard to serve as a darkroom containing processing dishes or sink, and a contact printer or an enlarger (or both) complete the set-up.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

There are large numbers of such small commercial studios specializing in photographs for catalogue and advertising illustrations. They are designed to handle small objects quickly and they are often squeezed into basements or out-of-the-way corners, because they try to get as near as possible to their clients, to be able to offer a quick and efficient service. Such work is usually required for reproduction, and nearly always has to be retouched before it goes to the blockmaker. So unless the studio includes retouching in its service it usually has a working arrangement with an outside commercial retoucher.

The Larger Studio. The larger commercial studios are completely self-contained with all the facilities for carrying out a wide variety of commissions without having to call in outside help. This calls for a much more complex type of organization which can handle teams engaged on both indoor and outdoor photography.

At the same time even the largest studios tend to specialize in some degree. A studio dealing with heavy industrial subjects, for instance, must be planned in terms of concrete floors, plenty of wall space, and easy access to the street, whereas a fashion studio spends its money on carpets, a reception desk, and dressing-rooms.

The Camera. Cameras taking large-size plates or cut-film are still used in some studios, especially for reproducing fine detail and for giving an opportunity for negative retouching. But it is becoming more general to use smaller negatives and print by enlargement. This in turn calls for additional darkroom facilities. Most studios have at least one camera, fitted with the whole range of camera movements, which can be used at any angle on a heavy commercial-type camera stand. At the same time there is usually a small folding camera, and a precision 35 mm. camera available for specialized photography.

Lighting Equipment. Lighting equipment varies considerably according to the work of the studio, but it usually includes a number of movable floodlights, and a bank of floods for general illumination, stand lamps for modelling, and focusing spots for adding highlights. As most studios now handle colour, all the light sources must be of the same colour temperature or be fitted with suitable lamp filters. It is no longer practical to mix daylight and artificial light, still less fluorescent lamps and half-watt lighting. Some studios nowadays do a lot of their work with electronic-flash operated from the mains, but in general, the lighting equipment of the commercial studio consists of the normal units sold for the purpose.

Some of the larger studios which specialize in colour work have extensive electronic flash equipment of high output. Such studios can frequently be rented, by the hour or the day, by the photographer who has only occasional need for this type of lighting.

Some electronic flash outfits incorporate into each lighting unit a tungsten lamp. This system enables the photographer to arrange his lighting visually, and yet to expose by electronic flash.

In a properly run modern studio, the number of trailing cables is kept as low as possible. Lighting units are operated from convenient wall fixtures, and the cables are suspended from above instead of letting them trail along the floor. In a studio of any size, there is at least one ceiling light (or bank of lights) for general top-lighting, mounted on runners fixed to the ceiling and pulled into position from below.

If the ceiling of the studio is low, it reflects a useful amount of light, but on the other hand a high ceiling gives more scope for manipulating top lights and spots.

Accommodation. In addition to the normal studios and darkrooms, a reception or conference room is an essential part of the establishment. This is used by clients who wish to have a say in the direction of the photograph—a situation that often arises when the studio is working on an advertising photograph that has to conform to a particular layout dictated by the agent, or when making catalogue illustrations of a new technical product with special selling features that have to be emphasized to satisfy the manufacturer. These activities must be kept separate from the normal routine work of the studio, and the premises must be laid out with that condition in mind.

Negative Filing and Storage. As time goes on, negatives accumulate so a reliable negative filing system is essential. The copyright of a photograph taken to instructions may belong to the client, but the negative is the property of the photographer. Re-prints may be required long after the picture has been taken, so every print and negative is given a reference and entered in a card-index system.

Storing the negatives so that they do not deteriorate and in accordance with fire regulations, is a major problem to the large commercial studio. The difficulty is made worse by the variation in size of the negatives, which may range from 8 × 10 glass plates, to 35 mm. cine film strips. Also the effort and additional work in extracting individual negatives and deleting them from the card-index (probably with cross references) is more trouble than leaving them where they are, so that over a period of years, negative storage may account for a considerable proportion of the studio floor space.

Models. Advertising photographs often include people, so the commercial studio must be able to call on the services of professional models. This means compiling a filing index of some complexity which must record the personal information about each model, and be kept

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

up to date. In addition to the model-register which each studio might possess, there are in the larger cities numerous model agencies, who provide models for all purposes. The agencies have photographs and details on all the male, female and child models (and even animals) on their books, and the photographer can pick the type who will best fill his particular needs. A studio must be ready to provide suitable models at short notice during the winter months for instance to stage a sunny picture advertising beach wear, or produce a cosy fireside picture in the middle of August. Such inquiries demand dressing-rooms, and plenty of floor space for the erection of simple sets. The range of effects is extended by using projected backgrounds—e.g., in the middle of winter a slide of a sunny garden with masses of flowers in full bloom may be projected to form a background for models displaying summer dresses, or enjoying a cool drink.

If the studio had to wait to take such photographs in actual sunshine, the summer would be over before the advertisement could appear.

"Props." The design and erection of studio-sets plays a major part in the make-up of the larger commercial studio. Smaller studios often work wonders with a few simple "props"—e.g., long wooden boxes that can be used horizontally as steps, or vertically as stands. A couple of "flats" are standard items in all studios for representing the corner of a room.

Backgrounds. Studios use both soft, roll-up backgrounds of painted canvas, and "flats" of three-ply or wall-board. The roll-up background has the advantage that it keeps clean when not in use; flats are stacked face-to-face for protection. Apart from a table with lamps available for photographing small objects, the studio floor is normally kept clear so that sets, corners, or short sections of wall can be built up as required with "flats" which may be either painted, distempered, or covered with wallpaper to suit the character of the interior represented. Odd flats are also used for preventing interference from the lighting of adjacent sets when more than one camera is in use in the same studio. The increasing use of colour means that any backgrounds used must be in perfect condition because it is no longer possible to touch out blemishes on the negative or print. The walls and most of the flats used in the studio are now coloured in light pastel shades which serve equally well as backgrounds for colour or black-and-white. One result of this is that nowadays the commercial studio is quite often clean and colourful. The flats, and even the walls, can be used also as reflectors. In the case of colour work it is, of course, only possible to use white surfaces for such purposes, as coloured flats would introduce a colour cast into the picture.

Retouching. Much of the work done in a commercial studio is required for reproduction, and retouching of prints and skilful use of the air-brush are part of the service. Most small commercial studios have an arrangement with an art studio where specialists will do the work; although in some of the larger studios there is an art department which also handles layout work and typography.

The air-brush is employed for ghosting effects where the important part of the picture stands out against a "misty" surround, and for reinforcing tones on large prints. When smaller prints and precision work are required, the photographs must be dealt with by an expert retoucher who is equally conversant with the use of an air-brush, knife and pencil. This form of retouching is often employed for colouring industrial pictures (colour retouching) and the fineness or boldness of the work must be in accordance with the requirements of block making and printing. Obviously the retoucher must have a working knowledge of the printer's art and be familiar with the methods of reproduction. B.A.

COMMON SALT. Everyday name used for sodium choride. Household salt is not necessarily always pure sodium chloride.

COMPENSATING DEVELOPER. Obsolete term still sometimes applied to M.Q.-borax and similar types of fine grain developer of low alkalinity, because the low gamma obtained compensates to some extent for high subject contrasts. In terms of gradation, the result is identical with that obtained by development to a low gamma in any normal developer.

More correctly, compensating developers should compress the over-all subject contrast in the negative, without greatly affecting the gradation in the highlights and shadows—yielding an effect analogous to tone separation. This often happens in two-bath development, where the action of the developer absorbed in the emulsion layer keeps up or even increases the contrast of the shadows, but does not appreciably increase the highlight density.

COMPENSATING POSITIVE. Low-contrast, low-density positive image on film or glass, bound up in register with the negative during printing in order to bring the tone range of an excessively contrasty negative within the range of the printing process.

Photographic Digital Preservation Foundation, Chandigarh

COMPETITIONS. Photographic competitions are of several types. Generally speaking the term is applied to those contests in which prizes are given.

There are competitions organized by the great national newspapers where prizes are offered, for example, for the best pictorial prints, the best sports picture, the best action picture, the best child portrait and so on. These competitions are generally run on well organized lines and the final selections are made by competent judges. Then there are commercial competitions run by manufacturers to increase sales of some particular product. In such competitions the purchase of the product is usually a condition. The competitor is asked to include a coupon or box lid or some evidence of purchase with the photograph. Many of these competitions are promoted by manufacturers of photographic products who award a prize for the best photograph taken with a particular make of camera or using a particular paper or film. Finally there are the competitions run by the photographic press in specialized subjects. These are organized to stimulate readership and to promote good photography generally.

Conditions for Success. A study of thousands of competition entries has shown quite clearly that the great majority of entrants, particularly for the national newspaper competitions, have little idea of what is required in order to win. Usually there is no limit on the size of the print submitted and for this reason the great majority of people send in contact prints of the $2\frac{1}{4} \times 3\frac{1}{4}$ ins. size or even smaller. Experienced entrants, however, generally submit a picture measuring half plate ($4\frac{3}{4} \times 6\frac{1}{2}$ ins.), whole plate ($6\frac{1}{2} \times 8\frac{1}{2}$ ins.) or even 8×10 ins. They know that the proprietors of the paper will want to reproduce the winning pictures in their journal and that it is much easier to judge a picture and to visualize it in its reproduced form when it is of a reasonable size. A certain number of very large pictures of what are generally called "exhibition size" are frequently sent in, but these stand no better chance than a whole plate print.

It should be obvious to any entrant that the picture must be clear and sharp and of a reasonable technical quality, but at least 75 per cent of the entries for the big national newspaper competitions are thrown out on the first sorting because they are thoroughly bad photographically. So before submitting a print, the sender should make sure that it is at least sharp, correctly exposed, and free from blemishes. Then the picture must make an immediate appeal to the average reader of the paper and should generally be simple in character and possess one main interest. Technical quality alone will not win a prize any more than good grammatical construction will ensure the printing of a story. A good sharp picture of a baby sitting on the sands with a spade and pail will stand no more chance than thousands of other similar pictures.

The type of photograph that wins prizes is a simple record of some particular incident with a strong sentimental appeal and the best training for success in this kind of photograph is undoubtedly to study the type of picture that is awarded the prize in similar competitions or in previous years. The judges in selecting the winning photograph always bear in mind that what is required is the picture that will have the maximum appeal to the paper's readers. If the picture has a strong appeal, slight technical faults may be overlooked.

In competitions designed to boost the sales of particular products the same general rules apply, but the picture should in addition create a desire to own the product. In fact, success in this field is largely dependent upon the photographer's sense of salesmanship.

In the general photographic competitions simplicity and direct appeal should again be aimed at and technical quality must be of the highest. The standard of a pictorial entry will be judged as keenly as for a picture entered at a salon or general exhibition.

All prints submitted to competitions should be black-and-white and on glossy paper for good reproduction. Rough paper prints, and particularly those which have been sepia toned, are almost impossible to reproduce satisfactorily. Finally, if the competitor wants his prints back, he should be sure to enclose suitable wrapping, stamped and addressed.

Copyright. The better organized competitions usually require that the winners of big prizes should make over the copyright of the picture to the promoters. This is reasonable when the prize offered is ten guineas or more, but entrants should beware of competitions, particularly for commercial products, in which one of the conditions of entry is that all entries become the copyright of the promoters. By making this condition, some firms will obtain hundreds of photographs for reproduction without having to pay any reproduction fee, simply because the pictures they use have not necessarily won prizes. The better competitions usually state that the main prizes call for the surrender of the copyright but in the case of all the other entries the copyright remains with the entrant. P.W.H.

See also: *Awards; Judging exhibition entries.*

COMPLEMENTARY COLOUR. One colour is said to be the complementary colour of another when the light of the two added together makes white light. A filter transmits light of its own colour, and absorbs the light of the complementary colour.

Negative/positive processes of colour photography produce first of all a picture made up of colours which are complementary to those of the actual scene, and then, by an extension of the same principle, give a final print in colours which are complementary to the negative and, therefore, true to the original subject.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

COMPOSITION

Composition is the tool wherewith the artist handles the subject matter at his disposal in the picture space so as best to express his purpose. His purpose is not always simply to please; he may wish to instruct, entertain, or even annoy. The subject matter by itself can do these things only to a limited degree; most of the virtue lies in the way in which it is presented by the artist.

The painter has the advantage of the photographer in being able to put in or leave out bits of subject matter at will. If anything present in the actual scene does not help to make his meaning clear, he can leave it out. If the purpose of the picture would be strengthened by adding something, he can add it.

Up to a point, the photographer can include more or less of the scene by changing his viewpoint, but eventually he must accept the contents of the picture space as he finds them. When that point is reached, his only remaining way of expressing his personal feeling about his subject matter is by emphasis—playing down some objects or aspects of them, and stressing others.

The things that control emphasis in a photograph are: tone, sharpness, scale, and arrangement.

Tone. If the tone of the subject is lighter or darker than that of the background and any other objects in the picture, the subject will tend to stand out from its surroundings and the observer's attention will naturally turn to it. If the subject itself is the picture, it is sufficient to show it well lighted against a plain background of darker tone, or if it is dark in tone, against a lighter background. But if the picture must include other items all more or less equal in tone, the principal item must be emphasized in some other way.

Sharpness. The photographer can direct attention to any part of the picture by making that part sharp and detailed and leaving the rest vague and blurred. This is one of the most useful photographic tricks for achieving emphasis and it is simply a matter of focusing the lens accurately on the part to be emphasized and throwing the rest of the picture out of focus.

Scale. All other things being equal, attention is held by the biggest single unit in the picture, whether it is an object or a mass of light or shade. To give the subject importance, it is useful to make it appear larger in proportion than the rest of the subject matter. The photographer can achieve this by altering the distance between the camera and the subject.

EFFECTS OF TONE. Tone differences make a subject stand out against its surroundings. Left: *Light subject, dark background.* Right: *Dark subject, light background. In both cases the separation is good and the subject contrasts effectively against the background.* Centre: *Subject tone and surroundings the same, resulting in poor differentiation.*

EFFECTS OF DEFINITION. Left: *With all parts of the sceen equally sharp, nothing stands out—the subject appears as a two-dimensional design.* Right: *Making the most important part only sharp (e.g., by differential focusing) isolates it, and adds an impression of three-dimensional depth. Such effects are best judged visually on a focusing screen.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

EFFECT OF SIZE. The relative size of an object influences its importance in the composition of the picture. **Left:** *Close camera position, and the subject dominates the picture area.* **Centre:** *Camera too close and the subject is of incidental foreground interest.* **Right:** *Distant viewpoint and the subject becomes part of the over-all picture arrangement.*

Everyone is familiar with the exaggerated proportion of hands or feet stretched towards the camera in close-up portraits. This apparent distortion of the truth is due to the way in which the lens looks at things—the closer they are, the more they are magnified beyond their true proportion.

bringing the camera close to it and decreased by choosing a more distant viewpoint. The relative size of an object can be emphasized or played down, according to its position in relation to other objects in the picture area.

For example, a group of people photographed at close quarters will show those standing near

EFFECT OF ISOLATION. The subject in a picture can be more clearly presented when isolated from irrelevant detail. **Left:** *In a mass of conflicting shapes, the subject is obscure and the pattern confused.* **Right:** *Concentrating only on the subject area and leaving out distracting details gives a clear result which is less confusing to the eye.*

In a photograph showing a row of telegraph poles along a road running away from the camera, the pole nearest the camera is almost twice the height of the next nearest, but a pole a quarter of a mile away seems no bigger than the pole on either side of it. This shows that the apparent size of the subject is increased by

the camera as giants and those farthest away as dwarfs; or cottages at the foot of a mountain may look right while the mountain itself is reduced to an insignificant rise. In such cases a more distant viewpoint will give a more normal set of proportions, and although this means accepting a smaller negative image, it

CONVENTIONAL PICTURE ARRANGEMENTS. **Left:** *Triangular construction conveying a sense of symmetry.* **Centre left:** *Circular composition, usually giving an impression of unity or repetition.* **Centre right:** *Diagonal arrangement, departs from the static effect and introduces stronger appeal.* **Right:** *Common L-shaped construction used in foreground framing.*

POSITIONS OF THE SUBJECT. For the most acceptable results visually, the subject may be positioned according to traditional recommendations. Left: Intersections of thirds are usually strong points of interest, especially the top left intersection. Right: Horizons are best either high or low in the picture; central division tends to create two pictures.

can always be enlarged in printing.

Arrangement. The subject receives importance from its position in the picture, that is, the place it occupies in relation to the other units making up the picture and to the actual frame of the picture. Arrangement in the picture space, like furnishing a room, is to some extent a matter of personal taste. But just as it would clearly be wrong to put a bookcase with its back to the light, or an easy-chair under a draughty window, there are rules of common-sense that can be applied in arranging the picture material and trimming the print.

When arranging the picture, the first common sense rule is to simplify the problem by cutting out all unnecessary bric-à-brac, however strong its sentimental value. Ruthless simplification makes the job of arrangement easier, and the meaning clearer and more direct.

Generally the only means of excluding unwanted material is the choice of viewpoint—a close viewpoint is often chosen because it cuts out a lot of background and surrounding objects; a low viewpoint, because it gets rid of fussy foreground and adds importance to the subject.

Having reduced the problem to its essentials, the next concern is to see that what remains helps the emphasis. All strong lines and shapes should as far as possible lead the eye towards the important part of the picture, certainly not away from it. A useful trick to give this sort of emphasis is to take advantage of the pattern into which the supporting details fall, or can be arranged, and to have the principal interest at the "strong" point of the pattern—at the top of a triangle, the centre of a circle, the inside of a spiral and so on. Such devices, however, are easier for the artist's brush than for the camera lens which must take things as it finds them.

Some thought should also be given to the balance of shapes in the picture. The principal shape should, ideally, be so positioned that it does not make the picture too heavily unsymmetrical. This is normally ensured by balancing the effect of the principal shape by a smaller, but stronger, tone in the other half of the picture.

Placing the Subject. The rules about placing the principal interest in the picture are straightforward and are as much rules of common sense as of art.

(1) Keep the subject away from the edges of the picture. If it is too close to any of the four edges, it will look uncomfortable, and there will be difficulty in filling the rest of the space without drawing the interest away.

(2) Keep the subject away from the geometrical centre of the picture. Central placing

EFFECTS OF DIRECTION. Left: Outward directions near the picture edge lead the eye away from the subject. Centre: Ideally there should be plenty of space in front of strong directional lines or movement to keep the interest in the picture. Right: Inward lines too near the edge lose emphasis and suggest that the important subject is outside the picture.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

EFFECTS OF BALANCE. *Careful relative positioning of important elements may help in balancing the composition.* Left: *This symmetrical arrangement achieves balance but lacks interest.* Centre: *Concentration into a single area creates unbalance.* Right: *Large elements may be balanced by smaller ones of more dominant tone.*

is useful for strong emphasis, but it is apt to be dull and formal. This is particularly so with the horizon, which should never be allowed to cut the picture space into two equal areas. Keep it well up or well down, leaving no doubt about where the interest lies—in the sky or in the landscape. If the horizon has no business in the picture, then cut it out completely and the picture will be rid of a strong distracting force.

(3) Allow more space in front of the subject than behind it. In a portrait, there should be more space in the direction of the sitter's gaze; a moving object should be shown moving into the picture and not out of it.

As far as possible these methods of controlling emphasis are applied when taking the photograph. It is always easier to cut out an unwanted bit of the scene by a change of viewpoint or camera angle than it is to get rid of it in the print. At the same time, the enlarging process does give the photographer a valuable second chance to improve the composition.

On the Enlarger. Ideally all the composition of the picture should be arranged at the time of exposure. In practice, however, this is not always possible.

Any necessary adjustment of shape and content to improve the composition can be made at the enlarging stage by increasing the magnification of the image until the unwanted part lies outside the margins of the paper. At this stage it is often possible to improve the composition of the picture by moving the paper about to bring the subject into a more favourable position in the picture area. So long as there is enough "air" around the subject on the negative it may even be possible to choose between a horizontal and vertical picture format as an aid to composition.

Sometimes the negative may contain enough suitable subject material to form the basis of two or even more separate pictures that can be composed in this way on the enlarger. In general, however, the main constituents of the picture should be selected and arranged at the time of taking; there is no merit in shooting indiscriminately and hoping to compose a picture at the enlarging stage.

Trimming. A final opportunity to improve the composition arises at the print trimming stage. As little as possible should be done here, however, because trimming means wasted paper and a smaller final print.

Retouching. The various methods of physical and chemical after-treatment of both negative and print afford another means of improving the composition of the subject. Unwanted objects may be removed by bleaching out or subdued by reducing. Tones may be modified to adjust the emphasis of tonal arrangements, and additional images—e.g., clouds—may be added by multiple printing.

Photography, like any other medium of self-expression, is a very personal thing. General rules on composition are usually valid, and a positive aid to better work. But the more advanced the artist or photographer becomes, the more he will instinctively realize when he should keep to the rules—and when he will achieve more by breaking them. F.P.

Book: *Composition in Pictures*, by R. Bethers (New York).

COMPOUND LENS. Lens unit made up of two or more individual glasses. The term is seldom used nowadays.

See also: *Lens History.*

COMPOUND SHUTTER. Central-opening type of shutter formed by a number of identical leaves mounted symmetrically around the optical axis of the lens. Invented by Friedrich Deckel of Munich, 1902.

COMPUR SHUTTER. Trade name of highly developed type of diaphragm shutter in which the speed of the operating mechanism is con-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

trolled by a clockwork escapement and, for the slow speeds, a gear train. The Compur shutter was devised by Friedrich Deckel of Munich in 1912, and his firm is still the sole manufacturer of Compur shutters. It was a development of the same inventor's Compound shutter introduced ten years earlier.

CONCAVE. Optical term applied to lenses and mirrors indicating that the surface is curved so that it forms a hollow.

CONCENTRATED DEVELOPER. Liquid developer in a concentrated solution that is diluted with water for use. Such solutions are more convenient to use than in powder form.

See also: *Developers; Solutions.*

CONDENSATION. When certain articles are brought from a cold atmosphere into a warm room, moisture forms on their surfaces. This is particularly evident with glass and metal parts, and is due to the condensation of moisture present as water vapour in the atmosphere.

Condensation can be very troublesome on photographic equipment, particularly lenses; even slight misting on a lens causes considerable diffusion of the image. Therefore a cold camera brought into a warm room should not be used until it has warmed up to the temperature of the room and the moisture on the lens has evaporated again. Condensation can often be removed by taking the camera out again into the cold for a short period, and is not likely to reappear when the camera is brought back into the warm room.

The same trouble occurs with enlargers kept under similar conditions.

See also: *Cold weather.*

CONDENSER. Optical system which concentrates the light from a source into a more or less defined beam, enabling the light source to be focused to any one position; e.g. into the lens on an enlarger.

A condenser consists of either a single plano-convex lens or a pair, with their plane sides facing out. It forms a very efficient light collector and can be adjusted to give suitably even lighting.

Use in Enlargers. A condenser or a condenser-diffuser type enlarger makes use of one, or more often, a pair of plano-convex lenses. Where only one such lens is used, the flat side is turned to the negative, and in fact is often used as a pressure plate to press down on the celluloid side of a film negative to hold it flat. When a pair of lenses are used, they are mounted with their convex sides facing and not quite touching. The mounting for double condensers must allow room for expansion due to heat.

Double condensers give the most even illumination and make for more compact lamp-design. Single condensers are used only because they are cheaper, and then only for the smaller negative sizes. The double lens system is always used for the larger negative sizes because, apart from any other considerations, single lenses would be inconveniently thick at the centre and would suffer from excessive spherical aberration.

The condenser must be large enough to extend well out beyond the corners of the negative. If it does not, the corners of the print will be darkened or even completely cut off. The diameter of the condensers should be slightly greater than the length of the diagonal of the negative.

Focal Length. The focal length of the condenser system is also important, particularly in a true condenser enlarger. Even in the condenser-diffuser enlarger the correct focal length is a great aid to even lighting.

The focal lengths of the condensers and the enlarging lens are directly related when used together. If a single condenser is used, it should be capable of forming an image of the lamp filament in the enlarging lens without an inconveniently great separation between lamp and condenser. If the image is formed at any other point, the enlarging lens will be able to project another image of this condenser-image on the print. The unwanted image may not be sharply focused, but it will be sufficiently real to make lighting uneven.

When the condenser-image of the filament falls within the enlarging lens, the enlarging lens can only see the condenser as an evenly illuminated disc of light, and this is exactly what is required for even illumination of the negative. To achieve this conveniently, a single condenser should have a focal length about half to the same as that of the enlarging lens.

The same conditions must be fulfilled by a double plano-convex combination. In this case the individual components should have a focal length of approximately the same to twice that of the enlarging lens, so that the focal length of the combination will be roughly half to equal to that of the enlarging lens.

Focusing. It has been said above that the image of the light source should be focused on the enlarging lens to give the most even illumination of the negative. But the condenser-to-lens distance varies according to the degree of enlargement: the lens is moved towards the condenser to increase the scale of enlargement and away from it to reduce the scale. So in a plain condenser enlarger the condenser must be re-focused every time the magnification is changed. This is commonly done by moving the lamp towards or away from the condenser. In some horizontal enlargers it is also possible to move the condenser.

When the lighting is a combination of condenser and diffuser, refocusing is not necessary for small changes, but it is always advisable whenever large changes of magnification are

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

made. For this reason the lamphouse should always provide for lamp adjustment.

Spotlights and Projectors. Condensers are also employed in spotlights and projectors. Spotlight condensers sometimes take the form of Fresnel lenses which have the same effect of concentrating the light in a beam. They are however much thinner than a full-sized condenser lens and are thus less liable to crack as a result of the heat of the lamp.

In projectors special cooling arrangements (e.g., a fan) are provided. G.W.A.

CONFERENCES

In these days of easy travel, conferences are on the increase, both on a national and international level. This also applies in the photographic field. One of the reasons is the continuing specialization in all fields of science and technology. Whereas at one time the Society Lecture was a well-attended feature, its importance has dwindled relative to that of the conference devoted to one or a few relatively narrow fields.

International Conferences. Photographic conferences are held on both national and international levels, but the differences between these tend to disappear. Starting in 1889, Photographic Congress was the organizing body of a series of nine international conferences, which set out to bring some law and order into nomenclature, copyright and manufacturing standards and gradually changed to scientific communication and discussion. The last of these was in 1935.

Since the last war, a string of informal conferences has been run in the sense that no central organizing body existed to plan and coordinate the meetings. At first devoted to all that was new in photographic science and applications, succeeding conferences became more specialized, and groups of specialists set out to organize their own meetings, such as those on nuclear-particle recording, high-speed photo-

* These symposia are perhaps borderline in not being truly internationally representative.
The tables omit conferences on specialized fields such as Astronomical Photography and Radiography.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

graphy and medical photography; here permanent secretariats were set up at least for the first two mentioned, thus providing a desirable degree of continuity.

The conferences on photographic science proper have undergone an interesting evolution. They first grew from an intimate colloquium to a vast assembly with parallel sessions, with all chances of fruitful discussion being drowned by the many papers presented. The tendency now is to reduce their size by limiting the number of subjects put up for discussion and to try out different methods of presentation.

An international gathering of photographic scientists at Brestenberg, November 1962, considered the following basic pattern of international conferences as desirable.

Congresses, devoted to all aspects of photography, should be held very infrequently. They might mark a celebration, and their purpose would be essentially social.

Symposia, devoted to a few chosen subjects, to be held every three years. Their purpose would be a mixture of social and scientific discussion.

Discussion meetings on very narrow subjects should be held whenever sufficient progress had been made. Attendance should be strictly limited, the purpose would be scientific discussion and, perhaps, the issue of a report.

A provisional International Committee on the Science of Photography (I.C.S.P.), with headquarters at Zürich, was set up charged with the task of pursuing these aims.

National Conferences. As national photographic science organizations grew in strength in the various countries, they began to run more ambitious conferences. The S.P.S.E. in the U.S.A., the recently created Science Committee of the R.P.S. (sprung from the Scientific and Technical Group), the Deutsche Photographische Gesellschaft, Sektion Forschung, and the Society for Scientific Photography of Japan have all been responsible for successful conferences. As they become known, they tend to attract international attendance, and the distinctions between national and international meetings are disappearing. There is certainly a need for a limited degree of co-ordination of all these endeavours. W.F.B.

CONJUGATE FOCI. (Conjugate Points). Name in optics for the associated positions of object and image in relation to the lens. For every position of the image there is a corresponding position of the object and these positions are interchangeable.

If the distance of each point is measured from the corresponding front (Df) or rear (Dr) principal focus of the lens (focal length, f) then:

$$Df \times Dr = f^2$$

See also: *Lens; Optical calculations.*

CONSTANT DENSITY RATIO LAW. According to Hurter and Driffield, relative densities measured over the different parts of a negative are decided by the exposure and not development. Any changes in the time of normal development can affect contrast only.

CONSTANT GAMMA EMULSION. Term indicating an emulsion which develops to the same contrast factor over the part of the spectrum being used, i.e., 2500–3750 A for ultraviolet spectrography, or 4000–7000 A for making separation negatives.

See also: *Gamma; Spectrography.*

CONTACT PAPER. Relatively slow development paper (usually a chloride paper) for making positives by contact printing.

See also: *Papers.*

CONTACT PRINTER

Equipment for contact printing is of three main types: frames of varying size for making single prints; boxes for quick repetition work and machines for bulk photographic printing, as in commercial photo-finishing or post-card production.

Printing Frames. The familiar printing frame is the simplest type of equipment for making contact prints from negatives. The sort used by amateur photographers is generally made from a hard, non-warping wood, like beech, although plastic materials have been used for small negative sizes.

The wooden printing frame carries a sheet of plain glass in a rebate. The back of the frame is detachable and is pressed against the glass by hinged spring arms which can be released to allow the negative and paper to be inserted.

In use, the frame is laid face downwards and the back removed. The negative is inserted, image side upwards, and a piece of printing paper laid on it, emulsion side down. If a white border is required around the print, a suitable mask is interposed between the negative and printing paper. When printing from glass negatives, the plate takes the place of the printing glass.

Exposures with printing frames are generally made under an electric lamp. A reading lamp is excellent for making occasional prints. The frame is laid face upwards on the table and the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

PRINTING FRAME. The parts, in order of assembly, are the frame itself, the glass (for film negatives), the border mask, and the back. In use the negative and paper are inserted between the mask and the back, and pressed into close contact by the springs which hold down the back.

lamp adjusted to throw its light down on to the front of the frame. In this way the lamp distance is kept constant and all negatives are exposed under the same conditions. Even illumination is essential. An opal or pearl lamp is satisfactory provided that it is kept at a distance of more than twice the diagonal of the negative away from the frame.

Large Frames. Printing frames for large negatives, 8 × 10 ins. or 12 × 15 ins., have to be much stronger than the amateur models. Because the negative is larger, the pressure applied must be greater to give good contact with the printing paper. Instead of wood, metal castings are often used to give the necessary strength, and plate-glass is used in the frame to stand up to the increased pressure which is applied by levers or screw-clamps.

Frames of this kind are used not so much for making continuous-tone prints from ordinary negatives (few photographers use negative sizes that large) as for a variety of graphic arts purposes. The frame there usually forms part of a printing box or other set-up with its own light source.

The limiting factor in this type of construction is the strength of the glass used in the front of the frame, and large sizes are apt to be heavy as well as expensive. For this reason it is usual to employ the vacuum principle to obtain the contact pressure in printing frames of the largest sizes, such as those used in printing from negatives of high definition or for printing-down in photomechanical work. In this, the frame carries a strong rubberized canvas pad or blanket with a heavy rubber beading. After loading the frame in the normal way, the blanket is pressed into contact with the printing glass around the edges of the negative, and the space between is evacuated by an air pump. The pump may be either hand-operated or electrically driven. The pressure of the air acts on the back of the blanket and the front of the glass, forcing the negative into close contact with the paper. Since the air pressures on the front and back of the frame are exactly counterbalanced, the printing glass and its frame can be of much lighter construction than where pressure is applied mechanically.

The contact obtained with a vacuum frame is much better than that given by a mechanical pressure frame since the air pressure is distributed evenly over the whole area. The frame can be opened instantly after admitting air to break the vacuum.

Miniature Frames. Miniature negatives on 35 mm. cine-film require special types of printing frame. One type is used for making contact prints on to strips of perforated 35 mm. paper or positive film, and the other for miniature lantern slides where the negatives are contact-printed on to 2 × 2 ins. plates.

For making diapositive films or film strips on 35 mm. film, the printing frame has a film magazine and a sprocket drive for feeding the positive film into position behind the negative in the gate of the printing box, one frame at a time. Negative and printing material (film or paper) are pressed into close contact by a pair of spring-loaded optically flat glass plates and exposure is made through the pressure glass by placing the printing frame under a lamp.

The magazine spools hold up to 10 or 12 feet of paper or film and the exposed material is cut off, removed, and developed in lengths of 5 or 6 feet in a drum-type processing outfit. Since exposures cannot be developed individually, this method of printing calls for considerable skill and judgement to produce an evenly-exposed strip of prints.

FILM STRIP PRINTERS. Left: Printing 35 mm. negatives on to miniature lantern plates. The negative film is spooled up and held above the illuminated gate of a light box, and the plate aligned in contact above it. Right: Printing on to positive film uses a similar arrangement, but needs a magazine, holding the positive film, on top of the negative.

CC-0. Jammu and Kashmir Digital Preservation Foundation, Chandigarh

The frame for printing lantern slides is much simpler. It is an ordinary frame for 2 × 2 ins. plates with a pressure pad and guides which keep the 35 mm. film parallel to the edges of the lantern plate.

Another special frame s used for printing stereo-negatives made in a stereoscopic camera. Such frames are sometimes known as transposing frames because the images from each pair of negatives must be interchanged before they can be viewed correctly in a stereoscope.

Luminiscent Printers. Some printing frames incorporate their own light source in the form of a luminescent panel. This yields a soft and even glow when the panel is connected to an electric supply. While the light intensity is low, the panel is in virtually direct contact with the negative so that all light is nearly 100 per cent utilized. Exposure times with such a panel accordingly are comparable with the printing exposures needed in a normal printing frame placed under a reading lamp.

Printing Boxes. The simplest printing boxes consist of little more than a printing frame with a self-contained source of illumination. Even so, they meet most of the needs of the average amateur photographer.

The cheapest type consists of a wooden box, painted white inside, with a light source provided by four flash-lamp bulbs, connected in parallel with a battery. An opening in the top of the box holds a glass plate backed up by a hinged, felt-covered pressure pad which presses the printing paper and negative tightly against the glass. A spring catch holds the pressure pad down, and when in this position, the bulbs can be switched on to give the necessary exposure to the paper. The box will take negatives up to quarter-plate size and black paper or red celluloid masks can be inserted to leave a white border on the print.

PRINTING BOX. Most designs feature a white exposing lamp fitted below a glass top with one or more diffusing sheets in between. The negative and paper are placed on the glass and pressed together by the hinged platen. An orange lamp (shaded) permits exact positioning before exposure.

Better boxes are made of metal and are fitted with a 40 or 60 watt lamp, run from the mains. The pressure pad is made to operate a switch, so that the lamp switches on to make the exposure as soon as the pressure pad is firmly in contact with the plate-glass printing bed. A small ruby lamp, which burns continuously, provides a safe light to allow the printing paper to be adjusted without risk of fogging. Masking bands on the surface of the printing glass can be adjusted to give a white border around prints of any size within the range of the box. A diffusing sheet of opal glass or plastic is generally interposed between the lamp and the printing glass to give even illumination, and suitably shaped pieces of tissue paper may be inserted between the negative and the light-source for local printing control. This type of printing box meets the requirements of the advanced amateur.

The professional printer must be able to turn out work of the very highest quality rapidly and easily and handle large negatives on both film and glass plates. For such work the illumination must be absolutely even, and strong enough for short exposures. The contact between negative and printing paper must be good enough to allow negatives of the highest definition to print without any loss of sharpness.

This type of printer is built to take negatives of any size up to 12 × 15 ins. Thin adjustable steel masking bands provide white margins on all prints up to this size. The pressure platen is made of hinged sections, faced with felt or soft rubber to distribute the pressure evenly over the area of the negative and paper. Specially selected flat plate glass is used to ensure intimate contact between negative and paper.

In general large-size printing boxes are nowadays used for special purposes only, such as printing X-ray films, making off-set litho masters from negatives or positives in photomechanical reproduction (especially at the small office offset level) and for document copying.

Illumination. There is a choice of diffused or direct illumination to suit the type of negative. Fully diffused illumination is used for negatives carrying heavy retouching or blocking-out. This type of illumination is usually provided by a bank of lamps behind diffusing sheets of ground glass or opal.

For high definition negatives or line subjects, direct illumination must be used to preserve the fine detail. Such lighting is given by a small light source placed some distance away from the negative. Even illumination is essential, so the printing light is fixed at a distance from the negative at least equal to its diagonal. The small light source may also be obtained by placing a pearl or opal lamp behind a 1 or 2 ins. diameter hole cut in an opaque baffle.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Printers sometimes have provision for varying the distance between the lamp and the printing glass to give further control of the exposure time. Other alternatives include interchangeable light sources of different intensity (from 15 watts to 1000 watts), or a variable step-by-step resistance in series with the printing light. By adjusting the strength of the light it is possible to print from a given negative on to any one of the four commonly used classes of printing paper (chloride, slow chlorobromide, fast chlorobromide, and bromide papers) and still give about the same exposure time.

Bulk Printers. Wholesale photo finishers use special printing machines for handling D. & P. and picture postcard printing. On such machines, everything possible is made automatic. The details of construction vary greatly according to the make and the output.

Reflex Printers. The reflex printer for copying documents is larger than most types of printer because it must be big enough to handle documents ranging from 8 × 10 ins. up to 30 × 40 ins. or larger.

A reflex printer is designed to give complete contact between the document and the printing paper, generally by the use of a heavy sponge-rubber pressure pad in conjunction with a rubber blanket. Large size printers use the vacuum system. A bank of lamps is generally necessary to give good, over-all illumination. In addition to the usual diffusing glass, there is a slot to hold a yellow filter when copying documents on a faded or yellow base.

Reflex printers are intended to be used by people with no knowledge of photography or printing; they are therefore simple, foolproof, and almost automatic. G.B.M.

CONTACT PRINTING

Contact printing is any method of making a photographic print in which the sensitized material is exposed in contact with the negative.

Mostly an artificial light source is used for this purpose; special printing papers are, however, suitable for daylight printing.

ARTIFICIAL LIGHT

Contact prints are normally made on so-called contact papers (formerly also known as gaslight papers) which are developed and fixed after the exposure to yield the visible image. Contact prints are usually made in a printing frame or printing box.

The prints are the same size as the negatives. They are usually black, but there are special warm tone papers which can be made to give warm black to red-brown prints and toners that can tone contact prints to any desired colour.

Papers are available in a range of paper grades, and can deal with negatives of almost any contrast.

It is always a wise plan to collect a batch of negatives for printing and then to do the job with ample quantities of developer and fixer under reasonably convenient working conditions.

Sorting the Negatives. Negatives should first be grouped according to their suitability for printing.

Unsharp negatives, also films or plates showing deep scratches, dark or light blobs, streaks, and areas of uneven density, are useless for print-making without some preliminary preparation. Very much under-exposed negatives with practically no shadow detail should also be thrown out unless they have been deliberately under-exposed—as, for instance, in night photographs.

The remaining negatives are then grouped according to their contrast and hence the grade of paper they will require to give acceptable prints.

MATCHING NEGATIVES AND PAPERS

Type of Negative	*Correct Paper Grade*
Very contrasty, consisting almost entirely of areas of black and almost transparent film or glass	No. 0 or Extra Soft
Contrasty, with strong blacks and fairly thin shadows	No. 1 or Soft
Average, with moderate contrast and tone gradation	No. 2 or Normal
Soft, with light grey shadows and medium grey highlights	No. 3 or Hard
Very soft (and often very thin), with little tone difference between the various parts of the image	No. 4 or 5; Extra Hard or Ultra Hard

The over-all density of the image does not affect the grade of paper that should be used; the paper grade is decided solely by the contrast of the negative. It is thus possible to have very dense and very thin negatives in the same contrast group. For this reason it may be worth while to classify the negatives in each group according to their density. This avoids big jumps in exposure times from one negative to the next within the same group.

The density may be judged by laying the negative on the page of a book printed clearly on white paper. Using this test, a negative in each group should then be chosen as a standard. It should show good tone and detail even in the thinnest areas, and the text underneath should be just readable, even through the densest areas. The negatives in the group can then be divided into four or five degrees of density with reference to the standard negative. It is much safer to estimate densities in this way than by looking through the negative at a bright light.

CONTACT PRINTING. Top and left: *Daylight printing on P.O.P. 1. Assembling negative and paper in the printing frame. 2. Exposure to daylight. 3. Washing. 4. Toning. 5. Washing. 6. Fixing. 7. Final rinse. 8. Drying.* Top and right: *Printing by artificial light on chloride paper. 2A. Exposure. 3A. Development. 4A. Stop bath. Stages 6 to 8 following here as for daylight printing (the fixer used is not, however, the same).* Bottom: *Exposure control by shading (to hold back part of the picture) and spot printing (to get more detail into areas corresponding to exceptional negative densities).*

Loading. During loading and processing the printing paper must be handled under suitable safelight illumination—generally yellow or light brown.

The printing frame is opened, the back taken out, and the negative inserted, emulsion side up. It is then covered by a sheet of printing paper, emulsion side down. The back of the frame is then replaced and clamped down, pressing the negative and paper into intimate contact.

If the print is to have a white border, a cut-out opaque paper or red celluloid printing mask is inserted in the printing frame in front of the negative. When printing from plate negatives, the glass of the printing frame is not needed.

To load a printing box the pressure plate is raised and the negative is placed, emulsion side up, on the glass window and covered by the paper. The pressure plate is then clamped down, pressing the paper and negative into close contact.

The emulsion side of the paper must be in contact with the emulsion side of the film or plate. If the negative is inserted the wrong way round, the layer of film or glass between the actual negative surface and the paper leads to a blurred print.

If the paper is inserted the wrong way round, the print will be even more blurred and it will also be very much under-exposed, since the light will have passed through the paper base. In both cases the right and left hand sides of the picture will be transposed.

Exposure. The exposure time required for a contact print depends on the paper speed, negative density, and the power and distance from the negative of the printing light. The actual exposure time is best determined by trial and error—initially with text exposures (see below).

With average contact papers suitable lamp distances are 7–8 ins. (20 cm.) with a 40-watt lamp, 12 ins. (30 cm.) with a 60-watt lamp, or 15–18 ins. (40–50 cm.) with a 100-watt lamp. Under these conditions, average negatives will call for exposure times around 5–10 seconds.

Negatives larger than $2\frac{1}{2} \times 3\frac{1}{2}$ ins. (6×9 cm.) should not be exposed nearer than 12 ins. from the printing light, and 5×7 ins. (13×18 cm.) or larger sizes should be at least 18 ins. away to avoid uneven illumination.

In a printing box the distance is in any case fixed by the design of the box.

Chlorobromide or bromide papers are very much faster than ordinary contact papers, so the printing distances have to be greater in proportion; they may be several feet.

For timing the exposures there is probably nothing better than a loud-ticking alarm clock. It is usually easier to count ticks by ear than to watch the seconds hand of a clock—particularly in the relatively dim light of the darkroom.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Alternatively, the exposure can be regulated by one of the many types of automatic timer. These switch the light off at the end of any desired interval.

Processing. After exposure the paper is removed from the frame or printer and it is then ready for development, which is basically the same as with enlarging papers. This can be carried out by subdued artificial light (no direct light must reach the print) or by a suitable safelight. The steps involved are:—

(1) Immerse the print in a suitable developer, and develop at about 65° F. for ¾–1 minute, moving the print in the solution all the time.

(2) Lift the print out of the developer, drain, and immerse in an acid stop bath for 10–15 seconds.

(3) Lift out, drain, and immerse the print in the fixing bath. Keep the print moving for the first half a minute or so.

(4) After 1 minute white light can be turned on for inspection.

(5) If two fixing baths are used, transfer the print to the second fixer after about five minutes. Move the prints about from time to time in both fixers and take special care that they do not stick together.

(6) After a further 5 minutes, transfer the print to a bowl of water for washing.

(7) Wash in running water for 1 hour or in about twelve changes of water, leaving the prints for 5 minutes in each change.

(8) If a hypo eliminator is used, immerse the prints in the eliminator solution for 10 minutes, moving them about all the time.

(9) Follow this by a further wash of 10 minutes.

(10) Drain the prints and lay them face down on a clean fluffless cloth, or squeegee them on a glazing plate for glazing (glossy papers only).

(11) Leave until dry.

Certain contact papers are designed for automatic processing in hand-driven or motorized roller processors. Such papers incorporate the developing agent in the emulsion. They are passed after exposure through a processing unit which applies an activator solution to the print surface (to develop the image) followed by a stabilizing bath, instead of a fixer. The completely processed and only slightly damp print leaves the processor within about 10 to 15 seconds, requiring only drying. Such prints are reasonably permanent, though not as stable as normally processed prints. Nor must they be hot glazed. However prints processed in this way can be made fully permanent by fixing in a normal fixing bath for about five minutes, followed by washing as described above.

Test Exposures. Once the grade of paper, strength and distance of the printing light, and the method of processing have been decided, the only variable factor that remains is the actual time of exposure for each negative.

The best time is found by making small test prints. A number of these are made from an average negative, with exposures of, say, 2, 4, 8, 16 and 32 seconds. The test prints need not be larger than about 1½ × 2½ ins. (4 × 6 cm.).

If necessary the exact exposure can be pinpointed after processing by using an exposure time between the times employed for a slightly too dark and a slightly too light print. If all prints are too light or too dark, the strength or distance of the printing lamp should be adjusted.

The test prints will also show whether the paper grade is correct: if the best print is grey and dull, without proper blacks or really light tones, the paper is too soft. If the print is too black in the shadows, and at the same time white and lacking detail in all the lighter areas, the paper is too contrasty.

As the sensitivity of different paper grades is not the same, a new series of test exposures must be made to find the correct exposure time whenever the grade of paper is changed.

After some experience, both print contrast and exposure can be estimated with fair accuracy so that there is no need to make a full range of test exposures every time unless for specialized work.

Local Exposure Control. In contact printing, a limited amount of local control can be exercised in the manner of shading and spot printing enlargements.

The hand or a suitably-shaped card can be held between the printing frame and the light to control the exposure of larger areas of the picture—e.g., the foreground in landscapes—and a card with a hole in it can be used for overprinting smaller areas.

In more elaborate printing boxes, movable masks can be inserted between the lamps and the printing stage to serve a similar purpose. In some multi-lamp printers the lamps can be switched on or off individually to vary the strength of the printing light over selected areas of the negative.

DAYLIGHT

Daylight printing is the simplest way of making prints because the image can be seen growing darker as exposure progresses. By inspecting the print from time to time it is easy to see when it has had enough exposure. Once the print has been exposed, it has only to be toned and fixed.

Exposures are rather long (up to ten minutes), and the prints are sepia brown in colour. Negatives for daylight printing must be contrasty.

The procedure consists of loading the printing frame, exposing, and processing.

Since daylight paper is only affected by comparatively prolonged exposure to daylight, it can be handled safely in subdued daylight or ordinary artificial light.

The paper and negative must be free from

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

any traces of dampness before they are loaded into the printing frame, or the soluble silver salts in the paper emulsion may form brown or black stains on the negative.

Exposing. The loaded frame is exposed to bright daylight—e.g., light from the blue sky—or even the sun. Exposures may vary from as little as 2 minutes in direct sunlight to as long as 30 minutes in normal daylight. The light on the frame must be even and free from irregular patches of shadow. Prints made in direct sunlight are usually softer than those made by diffused daylight.

High power mercury vapour and arc lamps may also be used for exposing daylight prints.

From time to time, one half of the hinged back of the frame is opened and a corner of the paper is turned back to check the depth of the image. The inspection must take place in very weak daylight and the paper must not be allowed to move in relation to the negative or it will give a double image.

The print loses density in the fixing bath, so exposure must be continued until the image looks a little too dark.

Processing. Processing consists of: washing, toning, rinsing, fixing, washing. Toning and fixing can be combined.

Self-toning papers need no toning bath; they are simply washed, fixed, and washed again.

The purpose of the first wash is to remove all the soluble silver salts remaining in the P.O.P. emulsion. These would interfere with efficient toning and fixing.

The exposed prints are washed for about twenty minutes in running water, or in about five changes of water. Some types of P.O.P. or self-toning papers may curl violently; these are best washed in a very shallow dish in changes of water. In this way it is easier to keep them flat.

Most tap water turns milky when silver salts dissolve in it. When successive changes of such water stay quite clear, washing can be considered complete.

The simplest toning bath for P.O.P. is a mixture of equal parts of 1 per cent gold chloride and 10 per cent ammonium thiocyanate solutions, diluted fifty times. Every 100 c.cm. (4 ounces) of such a toning bath will tone 700 square cm. (120 square inches) of print area. The toning solutions should be made up at least two hours before use.

An alternative toning bath consists of one part 1 per cent gold chloride and four parts 10 per cent disodium phosphate, diluted twenty times.

Toning time and tones obtained vary as the bath becomes exhausted. If a batch of prints is to have a uniform tone, all the prints must be toned together.

When the prints arrive at the desired tone, they are washed for about ten minutes in running water, and then fixed.

P.O.P. papers are fixed in a 20 per cent sodium thiosulphate (hypo) solution. Acid fixers must not be used.

The prints should be kept moving in the fixing bath to ensure free access of the solution and complete fixation. Prints should not be left in the solution for longer than about ten minutes, or they will begin to lose density. (At the same time it is useful to know that prolonged fixing will lighten slightly over-exposed prints.)

With self-toning papers, toning takes place during fixing, and no separate toning bath is necessary. Certain self-toning papers do not even require pre-washing; they can be put in the fixing bath straight after exposure.

With most papers, 100 c.cm. of fixer will fix about 1,500 square cm. of print area—i.e., 4 ounces to 240 square inches.

P.O.P. that is normally toned and fixed in separate baths may have both operations carried out in one combined toning and fixing bath. The prints therefore only need washing before treatment.

Combined toning and fixing baths must not be over-worked. This is because they still appear to tone satisfactorily after the bath is in fact exhausted. The image in these circumstances is not permanent.

A suitable formula for a combined toning and fixing bath is:—

Sodium thiosulphate	12 ounces	300 grams
Sodium chloride	35 grains	2 grams
Lead nitrate or acetate	35 grains	2 grams
Gold chloride, 1 per cent solution	2 ounces	50 c.cm.
Water to make	40 ounces	1,000 c.cm.

The capacity of combined baths is about 1,800 square cm. of print area for every 0·1 gram of gold chloride contained in the volume of solution used—i.e., 190 square inches for every grain.

Printing-out papers should be washed for at least one hour in running water, or in twelve to fifteen changes of clean water. They are then blotted and dried in the normal way, preferably by laying them face down on a clean towel.

Glossy gelatin daylight papers can be cold-glazed. L.A.M.

CONTACT SCREEN. Half-tone screen consisting of a regular pattern of unsharp dots, and used in contact with a continuous—tone negative to produce a half-tone positive suitable for photomechanical purposes. (Can also be used for obtaining a half-tone negative from a continuous-tone positive.) An increasingly popular alternative to the ruled half-tone screen.

See also: *Half-tone screen; Photomechanical reproduction.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CONTINUOUS-TONE IMAGE

negative print or transparency, which is composed of a range of densities from black through grey to white, and where the greys are formed by varying amount of silver, dye or pigment.

A continuous tone reproduction contrasts with a line reproduction which is composed of only two tones, black (or a colour) and white. The same applies to multi-colour line images; although there are several colours, each is present only in one depth. Nor is a photomechanical half-tone reproduction a continuous-tone image, since the illusion of tones is produced by varying areas (different sized dots) of printed ink on white paper, as in modern letterpress or photo-lithography. A half-tone reproduction simulates a continuous tone image since when viewed at the correct distance the tones appear to be the result of varying densities. On closer examination, however, it becomes obvious that the densities are in fact integrated areas of black ink and white paper. On the other hand, photogravure does give a genuine continuous tone image. Although a cell structure is superimposed for technical reasons, the tones are the result of varying densities of ink and not varying area.

Some photomechanical methods of reproduction are often described as continuous tone printing processes, such as Collotype. In many cases this is a misnomer. The tones of a Collotype print, for example, are produced by varying areas of black ink printed on to white paper from a reticulated gelatin surface. Owing to the irregular grain structure it is however difficult to break the tones down visually into the discrete areas of black ink and white paper; thus the tones appear to be varying densities.

Confusion can be caused in the use of the term in some European countries where continuous tone images are known (in literal translation) as half-tone images, half-tone screen images being simply called "screen" images.

D.A.H.

CONTRAST

In black-and-white photography, a difference in visual brilliance between one part of the image and another. Without contrast there could be no such thing as a visible image. A line in a photograph is visible only because it is either darker or lighter in tone than its ground. Every distinguishable part of the image is the result of a contrast in tone values.

Range and Scale. The difference in brilliance between the lightest and darkest tones in the picture is called its brightness range. The brightness range of a scene, negative, or print is expressed as the ratio of the brightest to the deepest tone.

The brightness range of an image tells only one thing about its character. A line drawing in Indian ink and a photograph may have the same brightness range, from black pigment or silver to white paper. But the line drawing has only two tones: black and white, while the photograph includes intermediate grey tones as well. In the same way, two photographs may be equal in over-all brightness range or contrast while one includes a large number of intermediate grey tones between black and white, and the other only a few.

The scale of tones discernible in a photograph governs its ability to give an impression of roundness and depth. To some extent, the black and white artist can overcome the monotonal limitations of his medium by shading effects in which he builds up intermediate tone values by shading and cross-hatching. He uses lines of varying thickness, more or less widely spaced according to the tones he requires.

So the artist can show the gradual change of tone that indicates a rounded surface, even though he is restricted to two tones—black and white—in applying the medium.

A photographic print does not express intermediate tones in this way. The depth of tone in a print is decided by the density of the silver deposit. In order to reproduce a full scale of tones from black to white the density of the deposit must vary in exact proportion to the luminosity of each individual tone.

COMPARISON OF CONTRAST RANGES. 1. An average subject may consist of a house of light tone in sunshine with shadows, with a range of 160 : 1. 2. The negative records all the tones. 3. A paper print can only reproduce a portion of the range. 4. A transparency projected on screen shows increased shadow detail. 5. A transparency lit from behind is the only positive reproduction that can encompass the full original range.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

In practice the tones of the picture may proceed from black to white in a small number of steep steps or a large number of shallow steps. The first results in a hard, boldly defined picture with only a few clearly recognizable tones—say black, dark grey, middle grey, pale grey, and white. This is known as a hard or contrasty print.

The second gives a print in which there are no sudden changes from dark to light tones and in which the eye can recognize a large number of tones of different depths of grey. A picture of this type can reproduce the gradual change of light over a rounded surface and the delicate differences in tone between near and more distant objects. This is known as a soft print. At the same time, since there are no strong contrasts, the picture loses brilliance and strength. It may even appear flat and dull.

For this reason the photographer generally aims at producing an intermediate type of print with enough tones to give modelling but not enough to destroy firm definition and clarity. In other words, a normal print.

Subject Contrast. The brightness range of the subject and hence the contrast of the picture it presents to the camera can vary within very wide limits. A scene where there are whitewashed walls in sunlight and, say, dark paintwork in shadow, might have a brightness range of 160 : 1, while the range of a calm seascape under an overcast sky might be only 2 : 1. A scene with a brightness range of 60 : 1 viewed in cross-lighting might not exceed 20 : 1 in frontal lighting where no shadows are visible. The brightness range of a subject seen against the light is always extreme, but it can be greatly reduced by fill-in lighting.

Negative Contrast. The brightness range of a negative can never exceed a ratio of about 200 : 1 because the clear parts are never completely transparent and the blackest parts are never completely opaque.

How contrasty any particular negative may be is determined by the contrast of the original subject, by the type of emulsion used, by the characteristics of the developer, and by the time of the development.

A contrasty subject tends to give a contrasty negative, although by suitably varying the characteristics of the developer or the time of the development it is possible to produce a contrasty negative of a soft subject or vice versa.

Print Contrast. The contrast of a glossy bromide print can never be more than about 60 : 1 and it is generally very much less because the whitest highlights are always slightly veiled, and the deepest shadows are never completely black. In practice the contrast of the picture will depend on the contrast of the negative and on the paper grade. It is also affected by the texture of the paper surface. Matt and rough textures scatter light and so give less deep shadows than a glossy or glazed surface, thus shortening the contrast range.

SUBJECT AND NEGATIVE CONTRAST. A, subject of normal brightness range. B, reproduction of subject tones on negative material of normal gradation. C, reproduction on contrasty negative material (either shadow or highlight gradation is lost). D, reproduction on soft gradation material (negative has no very high or low densities).

Subjective Considerations. Contrast as measured, say, by a densitometer is by no means the same thing as contrast as it is finally perceived by the human brain. For example the eye may fail to perceive a range of delicately graduated tones in a photograph which also contains a strong patch of brilliant light or deep shade. It may be much more affected by a white image on a dark ground than by an identical dark image on a white ground, although the measured contrast would be the same in each case.

Again, the ability to discriminate between tones—and therefore to perceive detail and form—varies between one observer and another. It may even vary in the same observer; if he is familiar with the subject and knows what to look for, he is more likely to be able to see significant detail in it than if he has no idea of what he is looking at.

Colour and Contrast. Finally the colours of the scene can alter the whole character of its contrasts as they appear to the eye. As the sensitized material does not respond to colours in the same way as the eye, the final positive print may present a picture of different contrast from the original scene.

If the print contrasts are to be as close a representation as possible of those of the original scene, a colour filter in front of the taking lens can be used to hold back those

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

colours which affect the photographic emulsion more than they do the eye. The commonest example of this is the use of a yellow filter of a suitable depth of tone for correcting the over-sensitivity of the emulsion to blue. For example if the scene includes a blue sky with white clouds, the blue sky is liable to reproduce as light as the clouds, and the two will merge in the print; the filter restores the contrast.

On the other hand, where adjacent areas of the subject differ in colour but not in brightness, it is possible to make the colour contrast visible as a tone contrast. This requires a filter to distort the true tone values and make certain colours come out either darker or lighter in the black-and-white print than they would appear to the eye. The use of such contrast filters is common in medical and document photography and in the photomicrography of differentially-stained specimens.

Wherever flat frontal lighting is unavoidable—e.g. flash on the camera—there are no shadows to accentuate texture and modelling. In such cases, the only way of reproducing important detail may be to exploit the colour contrasts in the subject by the use of filters—or by taking the photograph on colour film.

Colour materials generally show the same response to the spectrum as the eye so that the colour contrasts of the print are usually a fair representation of what the eye would see in the subject.

For this reason flat lighting, while uninteresting in a black-and-white photograph, is successful in colour—and even recommended by the makers of colour materials because it keeps the brightness contrast safely within the range that the colour film can handle.

From all this it is clear that the subject of photographic contrast is complicated by a number of subjective and psychological factors, by personal idiosyncrasy and by the nature and context of the scene.

It is a matter of first importance to all photographers because it controls print quality and decides the whole character of the finished photograph. But much of its effect must be learned by observation and experience. It cannot be mastered simply by being measured with a densitometer. F.P.

See also: *Characteristic curve; Contrast control; Gamma; Papers.*

CONTRAST CONTROL. Some control of the contrast of the negative is possible during processing.

There are also various ways of controlling the contrast of the final photograph by modifying the normal technique during enlargement, or when processing the print.

Control in Negative Processing. The two main means of controlling contrast are the choice of developer and degree of development.

Energetic developers will give high contrast especially the caustic hydroquinone type of formula as used in process work. Soft-working developers, including most fine-grain types will give low contrast images.

Prolonged development also increases the image contrast, while shortened development decreases.

The maximum contrast obtainable in each case depends on the negative material employed.

Special techniques like two-bath and water-bath development also afford a measure of contrast control.

Control by Masking. The contrast of the negative can be effectively altered by making a weak positive transparency from it, and of different contrast. This is then bound in register with the negative before the print is made. The technique is known as masking, and although involving extra work, is capable of producing a wide range of results that can be strictly controlled.

In particular, masking is of special value in making colour prints or duplicates of colour transparencies.

Control in the Enlarger. The type of enlarger illumination to some extent controls the contrast of the projected image. But it is not practicable to use the enlarger illumination as a means of contrast control, because this would mean changing the lamphouse and the optical system.

One practical system of contrast control in the enlarger is to use a printing light of variable colour in conjunction with a variable contrast paper. The latter produces prints of low contrast when the printing light is rich in blue, and higher contrast as the light becomes increasingly yellow.

The colour of the light can be controlled by using a range of interchangeable filters. The filters may be balanced for high efficiency enlarger lighting, and each have the same filter factor, so that the printing exposure is unaffected by changing the filters.

Part of the exposure may be given through a filter of one colour, and the rest through a filter of the colour giving the opposite contrast effect. This method gives a continuous range of contrasts from hard to soft.

On some enlargers an automatic mixing device combines the light of two different colours, again yielding a continuous range of contrasts.

A different procedure, widely used in photofinishing laboratories, entails the use of a hard paper grade all the time, the contrast being reduced by a controlled fogging exposure before, during, or after the printing exposure. The relative exposure times are balanced by a suitably calibrated control.

A modern printing method with automatic contrast control uses a flying spot scanner

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

(produced by an electron beam on a cathode ray tube) as the light source. This scans the negative in the manner of a television image, while the light coming through is monitored by a photo-multiplier tube. With the aid of a suitable electronic circuit this tube controls the brightness of the scanning spot all the time, and so adjusts effective printing exposure to the negative density over each part of the image. The feed-back of the photo-multiplier tube is variable, giving any desired degree of contrast reduction or increase. The necessary apparatus is complex and comparatively expensive.

Control in Print Processing. Some local control may be exercised during development by applying concentrated developer to the print locally with a plug of cotton wool. This often gives some increase in local density and contrast. But the actual degree of control possible in this way is very small.

One way of controlling the over-all contrast of the print is to choose a developer with suitable characteristics. Otherwise, of course, there is the more normal course of using a different paper grade—or even a different make of paper.

Hydroquinone developers give slightly higher contrast than a standard metol-hydroquinone formula. By the same standard metol developers give prints of rather lower contrast. The range of control made possible by the use of pure metol, or pure hydroquinone developers, is usually equal to just under one paper grade.

Three stock developers consisting of pure hydroquinone, standard metol-hydroquinone, and metol formulae, give the whole range of control available by this method. There is nothing to be gained by using intermediate mixtures.

With a standard metol-hydroquinone formula, the strength of the solution also has some slight effect on contrast; the more concentrated the developer, the more contrasty the result.

For very close control of contrast the developer may even be changed during development. The print is made on the contrast grade estimated to be most suitable, and development is started in a metol-hydroquinone developer solution. If the image, as it begins to appear, seems too soft, the print is transferred at once to the hydroquinone developer. If it appears too hard, it is put into a metol developer, and development finished there. The sooner the print is transferred to the soft or contrasty developer, the more marked the effect.

This method calls for experience in judging the contrast of an under-developed print; this is not necessarily the same thing as the contrast of the finished picture.

The developers very quickly become contaminated in the process of changing over prints from one to the other. For this reason it is better to work with small quantities and renew the baths frequently rather than continue to use a comparatively large volume of heavily contaminated solution. L.A.M.

CONTRAST FILTER. Filter that is used to lighten or darken the tone of a particular part of the subject in relation to its surroundings, as opposed to a filter employed to reproduce each tone in its normal visual brightness. Any colour filter can be employed as a contrast filter.

CONTRAST GRADES. Bromide, chlorobromide and contact (gaslight) development papers are manufactured in a range of grades of printing contrast. The number of grades varies with the maker of the paper and the type.

See also: *Papers.*

CONTRAST TRANSFER FUNCTION. Alternative term for transfer function, describing—in the case of an optical or photographic system—how the response of the system to fluctuations in exposure depends on spatial frequency (i.e. the fineness of detail to be resolved). This function—usually in the form of a graph—enables the overall performance of photographic systems to be measured and compared.

See also: *Information in the image.*

CONTRE JOUR. Term used to denote a photograph taken with the camera pointed towards the light source. Contre jour pictures are notable for the halo effect usually produced around the edges of the subject. Because photographs of this type have an extremely great brightness range, they need careful exposure.

See also: *Against the light.*

CONTROL PROCESSES. In the early days of photography the shortcomings in contrast range and colour sensitiveness of plates and film caused photographers to look for printing processes that would give them some control over the tone values of the picture. The pigment processes answered the need of the time and some of them continue to be used to-day. In the pigment processes the image is developed in light sensitive gelatin or gum, loaded with a suitable pigment. During development the pigment is removed from the highlights, revealing the white paper base. The amount of pigment removed is under the control of the photographer, and in some processes extra pigment can be added to the shadows, giving very full control over the final tones.

Many of the processes have to-day little more than historical interest, but others have been improved, and are still employed to a limited extent.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

BASIC CONTROL PRINTING PROCESSES COMPARED

Name	Type	Control	Remarks
Bromoil	Bromide print image bleached out and converted to relief image: this accepts ink or pigment	Hard ink applied by brush, strengthens shadows. Soft ink softens lights and contrasts. Ink applied in different depth. Highlights picked out with soft rubber. Unsightly objects can be removed	This process needs some skill and experience before it can be used with success
Bromoil Transfer	The inked bromoil print may be used to transfer the pigment image to a sheet of plain paper by passing this through a roller press in contact with the inked print	None at this stage	Prints very attractive and are more delicate than the bromoil. Care is needed—and experience—before the process is mastered
Oil Process	Gelatin coated double transfer paper as used for carbon printing is sensitized with bichromate and exposed by daylight in contact with negative. When a brown image is seen with shadow detail, print is washed in running water until stain disappears. Then dried print soaked and ink applied with brush as for bromoil	In application of the ink by a patting action on the print. Detail will be built up and density attained	This process has largely been superseded by bromoil, which allows a small negative to be used for enlarging
Gum Bichromate	Print sensitized by coating of bichromate, gum arabic and pigment. Print exposed under negative by contact in daylight or to mercury vapour lamp. Developed with water	Application of water to the image by spray or gentle jet reduces depth. For more rapid development warmer water may be applied locally. Gentle brushing will also emphasize highlights	Prints may be made in any colour pigment. Considerable skill needed to master the process. Has largely been superseded by bromoil, as control is effected more easily

With the improvements that have been made in bromide papers and the almost universal use of small negative sizes, many printing processes that were formerly popular have gone out of use. The more important of these are mentioned in the table.

The only important pigment or control processes in use today are carbon, carbro, gum bichromate, bromoil. Of these, only gum bichromate and bromoil permit really selective control. There are numerous other processes which allow varying degrees of control; some of these are obsolete variations of a basic process, others are modern processes which, although not intended as control methods, do provide some incidental manipulation. Of all these, the most well-known processes—by name at least—are as follows: arabin, Artigue, broloid, dusting on, Flexichrome (a modern hand-colouring process), Fresson, gum platinum, ozobrome, ozotype. R.M.F.

CONVERGING LENS. Lens which is thicker in the middle than at the edge. It has at least one convex surface. Rays of light passing through a converging lens are refracted towards the optical axis. A converging lens is capable of forming a real image, i.e., that can be focused on a screen. Converging lenses are also known as positive lenses.

See also: *Lens; Supplementary lens.*

CONVERGING VERTICALS. When anyone stands in front of a tall building and looks up at it, the vertical lines appear to converge as they get farther away. At least, they converge in the image on the retina of the eye.

But we know that the sides of the building do not really converge, so the brain refuses to see them that way. Furthermore, the whole of the building is not seen at once; the eye travels up and down and the brain adds up all the impressions. So it has time to cheat itself over the discrepancy between the width at the bottom and that at the top.

But when a camera looks up at the building, it records it as it appears to the lens. And it does it with a single glance. When the brain is confronted with the true state of things on a reduced scale so that the eye can take it in as a single impression, it refuses to accept it. In some way the picture looks wrong. But if the photograph shows the sides of the building parallel (as they could never appear from an angle) the brain is satisfied and the picture looks right.

In taking the photograph, the true picture can be distorted to get one that is acceptable. This is done by first setting up the camera with the negative plane vertical and parallel with the front of the building. This ensures that the vertical lines will be parallel, but it also means that the top part of the building lies off the negative. So the rising front is brought into action, sliding the lens up until it brings the whole of the building into the picture.

If converging verticals have not been adjusted in the camera, they can be corrected during enlarging by tilting the paper easel, and the negative carrier, or tilting the paper easel and the enlarger lens. Tilting the easel alone will

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

correct the verticals, but will prevent overall sharpness from being retained over the print.

Tilting the Paper. The vertical lines of the picture can be made to run parallel by raising the paper holder or masking frame at the edge towards which the lines of the projected image diverge. This decreases the degree of enlargement at the raised end of the paper and, within limits, it is possible to adjust the tilt until the lines run parallel to each other and to the sides of the picture. But because the surface of the paper no longer lies in the same focal plane, the image will no longer be uniformly sharp. So the image is first focused so that it is sharp in the centre of the field, and the lens is then stopped down until the depth of focus extends far enough to give sharp definition over the whole of the image. But stopping down will rarely in practice be sufficient, unless an appropriate tilt of negative carrier or lens panel is also used.

Another consequence of the tilt is that the image gets progressively brighter as the distance between the lamp and the paper decreases. So it is necessary to give the paper progressively less exposure as it comes closer to the lamp. This is done by shading the enlargement during part of the exposure.

Tilting the paper also has the effect of stretching out the image in the direction of the lines that have been made parallel. The elongation is only important in scientific photography; it is rarely as objectionable in pictorial work as uncorrected verticals.

CORRECTING DISTORTION. Top: *Pointing the camera upwards at a building makes verticals converge.* Bottom: *Tilting the paper holder during enlarging makes the converging lines parallel, but usually distorts the original proportions.*

CORRECTING DISTORTION. Top left: *The degree of distortion due to straightening verticals in enlarging depends on the distance A which is normally fixed for a given enlargement.* Top right: *Tilting the lens alters the lens-negative distance B to permit approximate correction.* Bottom left: *An alternative method is to tilt both negative and baseboard in opposite directions to each other.* Bottom right: *In this case a new lens-negative distance C for more correct representation is obtained by sliding both negative and paper sideways.*

Tilting Paper and Negative. The amount of possible correction can be doubled if the negative carrier also is tilted. The direction of tilt should be opposite to that of the paper, so that the side of the negative towards which the lines converge comes nearer to the lens—i.e., the negative carrier is lowered at the side on which the paper holder is raised.

This method of correction preserves the negative-lens-paper relationship, so that the image can be focused sharply over the whole area without stopping down the lens. The projected image will be perfectly sharp so long as the planes of the negative and the paper intersect in the plane of the lens.

Since the tilted paper is still farther away from the lamp at one side than the other, progressive shading is still necessary during the exposure.

The extent to which the image is elongated or compressed, depends on the lens used and on the scale of magnification.

Accurate Correction. For exact work—aerial, architectural records, etc.—no distortion of the image proportions can be tolerated. But the necessary accuracy is only possible under specific conditions of compensation; the focal length of the enlarger lens must be greater than that of the camera lens used in making the negative, and a definite degree of enlargement must be used depending on the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

focal lengths of camera and enlarging lens.

To correct converging verticals without image distortion, the degree of enlargement required is given by the equation:

$$M = F_e / \sqrt{(F_e)^2 - (F_c)^2}$$

where M = Degree of enlargement
F_e = Focal length of enlarger lens
F_c = Focal length of camera lens

If prints are required on any other scale of enlargement than this, a duplicate negative must be prepared at this magnification, and prints made from it in the normal way. The greater the focal length of the enlarger lens, the smaller the magnification required for the duplicate negative. L.A.M.

Books: *Basic Photography*, by M. Langford; *The Complete Art of Printing and Enlarging*, by O. Croy (both London).

CONVERTIBLE LENS. A convertible lens is made of two lens assemblies which can be used separately or together. Such lenses are usually of the symmetrical type.

When the separate lenses have different focal lengths—as they usually have—there is a choice of three different focal lengths. To use the rear component alone, the front one is simply unscrewed, but when the front component is used alone it has to be screwed into the back of the mount in place of the rear component to bring it behind the stop.

Changing over from one arrangement to another alters the effective aperture as well as the focal length. For example, a lens may have a combined focal length of 12¼ ins. at *f* 6·8, and the component parts used alone give lenses of 26½ ins. at *f* 16 and 19 ins, at *f* 12·5.

Interchangeable Lens Systems. The principle of the convertible lens is also the basis of one kind of interchangeable lens system used by a few makers of 35 mm. cameras. In these cameras a fixed rear lens component is associated with a number of interchangeable front lens components which convert it to short, normal, or long focus as required. Where the camera has a between-lens shutter a single shutter mechanism may be incorporated in the fixed part.

Supplementary Lens Units. Corrected lens assemblies are made to combine with standard camera lenses to shorten or lengthen the focal length.—i.e., to produce wide angle or telephoto combinations. These supplementary units fit in front of the standard lens. In one case the standard lens is removed from the camera and fitted in front of the auxiliary lens. The result is an increase or decrease in the focal length of the standard lens depending on the characteristics of the auxiliary component.

See also: *Afocal lens; Lens, interchangeable; Supplementary lens.*

CONVEX. Optical term applied to a surface, e.g., of a lens or mirror, which bulges outwards at the centre.

COOKE TRIPLET. The Cooke Triplet was designed by H. D. Taylor in 1893. It was a complete breakaway from tradition, and was the basic design from which many of the leading camera lenses have been developed. In its simplest form, the Cooke Triplet uses three glasses arranged as a compound front and a single back element. The front element consists of a converging crown glass and a diverging flint glass with a small separation. The back element, widely separated from the front, is a converging crown glass.

This lens was originally manufactured in apertures up to *f* 6·3, but other lens designers have since used it as a model and improved its performance.

Zeiss replaced the single back element by a compound lens to make the now famous Tessar lenses with apertures up to *f* 2·8. A further modification of the back element gave the Ross Xpres.

Many of the well-known lenses derived from the Cooke Triplet are complicated and expensive. In its simplest form it gives a maximum aperture of *f* 6·3 and will cover a plate with a diagonal equal to the focal length of the lens. To improve on this performance, the single elements have to be replaced by more or less complex assemblies of glasses which naturally add to the cost.

COOPER, JOHN THOMAS, 1790–1854. English resident chemist of the Regent Street Polytechnic. Read a paper before the Royal Society of Arts on 19th May, 1839, which was the first account of the production of sensitized material on a comparatively large scale. The title of this paper was *The Preparation of Photogenic Paper.*

COPPER CHLORIDE. Cupric chloride. Used in bleachers, some toners, intensifiers and reducers.

Formula and molecular weight: $CuCl_2.2H_2O$; 171.

Characteristics: Green hygroscopic crystals.

Solubility: Highly soluble in water.

COPPER SULPHATE. Blue vitriol; cupric sulphate. Used in bleachers, some toners, intensifiers and reducers.

Formula and molecular weight: $CuSO_4.5H_2O$; 249·7.

Characteristics: Blue crystals.

Solubility: Freely soluble in water at room temperature.

COPPER TONING. Method of toning bromide prints with copper ferricyanide which gives a wide range of warm black to purplish-red tones according to the time of immersion in the toning bath.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

COPYING

Copying is the process of making photographic reproductions of graphic art, manuscript or printed matter—e.g., paintings, drawings, photographs, documents, postage stamps.

In such cases the aim may be to produce a photographic print which can be used instead of the original, either because the original is too precious or fragile to be exposed to everyday handling, or because it is too large to handle or sometimes too small—e.g., postage stamps. But the commonest reason, of course, is that any number of prints or reproductions for distribution may be made from the negative.

Photographic negatives may be copied for any of the above reasons, and also as a way of altering the tone scale, density or some other characteristic.

Approach. The normal procedure requires that the copy should be evenly illuminated, and that the camera should be perfectly square to the copy (i.e., so that the plate or film plane is parallel to the copy). The correct exposure must be then determined, and after exposure the sensitized material must be processed to suit the contrast range of the original. The only other consideration that may be necessary is that of scale: it may be desired to reproduce the copy to a pre-determined size.

Other special requirements exist when dealing with special subjects. For instance, in copying manuscripts and old documents, severe limitations may be imposed on the handling of the copy, making it impossible to adopt a normal procedure; in photographing oil paintings, it may be required to emphasize the texture of the oil paint. Such specialized subjects are separate techniques in their own right and are not considered here in this more fundamental account of copying procedure.

Equipment. It is not always necessary to use a camera to reproduce documents or line drawings. These may be printed by contact: examples are blue-prints and dye-line, widely used in drawing offices.

Reflex copying may be used for originals on thick paper, or documents printed on both sides. This is a variation of contact printing in which the sensitized paper is placed on top of the original, emulsion side down. On exposure the light passing through the sensitized paper is reflected back by the white ground of the document but not by the ink. This therefore yields a paper negative from which positive copies can be made by normal contact printing.

Special equipment and materials for these processes are produced and widely used in industry and commerce.

If the original has to be enlarged or reduced a camera must be used. Some copying machines, for example, incorporate a special camera and make copies up to 18 × 24 ins. from 36 × 48 ins. originals, using bromide paper as negative material—usually processed in the machine.

Other commercial copying systems are used to make copies of small size for filing and storage, some producing half-plate or whole-plate negatives on sheet film from drawings and large documents. Micro-copying outfits record smaller originals on 35 mm. film.

From the technical point of view the basic requirements of camera copying apply equally to the photographer making occasional copies with improvised apparatus as to commercial systems.

The essentials are that the subject must be perfectly flat, at right angles to the optical axis of the lens and parallel to the plane of the sensitive material. This condition is met conveniently by a copying stand analogous to an enlarger. The camera is mounted on either a vertical column or a pair of horizontal parallel

COPYING SET-UP. **Top:** *For even illumination the lamps should be at the same distance from the original, to each side of the camera, and make the same angle (about 45°) with the lens axis.* **Centre:** *The lamps should also be in the same plane as the lens axis.* **Bottom:** *A vertical stand takes up less space, but tends to be less rigid. In all cases the lens must point squarely at the original, with the plate or film parallel to the copying surface and the lens axis at ri ht an les.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CAMERA ALIGNMENT. Top: *A baseboard marked with diagonals is a useful aid to centring the camera accurately above the original to be copied.* Centre: *Once the image is centred on the focusing screen of the camera, a plumb line will show whether the optical axis of the camera is at right angles to the baseboard.* Bottom: *Pencil test for even illumination. If both lights are equal in intensity and distance from the centre, the shadows on either side of the pencil will be equal in tone. If both lamps are at the same angle, the shadows will also be equal in length and position indicating good alignment.*

guide rails in the same way as the head of an enlarger.

Anyone who possesses an enlarger can convert it into a copying stand by simply removing the head and fixing the camera in its place. Some miniature camera systems are planned so that the camera or a focusing stage can be substituted for the enlarger head in this way: others have special stands.

The camera must be equipped for close up focusing by means of long bellows extension, extension tubes, or supplementary lenses.

For the best quality reproduction a plate camera of reasonably large negative size is normally used. An 8 × 10 ins. camera with adapters for smaller plates makes an excellent copying camera. For documents the copy can be made direct on to one of the document copying papers, which saves the cost of a plate. Negative materials for copying, too, are mainly produced in plate or sheet film form, so that a plate camera can best cope with all kinds of work. Ideally it should have a focusing back, since this is more convenient than front focusing when working close up.

Miniature cameras are widely used for copying documents and small drawings on 35 mm. micro-copying film. Rollfilm cameras are largely unsuitable since special negative materials are not available. However, adequate line and half-tone copying is often possible using the slowest films, processed for maximum contrast.

Sub-miniature cameras have the unique ability of being able to make legible copies of documents, drawings and pictures without any of the normal elaborate technical preparations. This is because the great depth of field of the subminiature lens makes accurate focusing unnecessary even at full aperture. So the camera can be held in the hand and the copy made with a short instantaneous exposure. This facility for quick, unobtrusive copying makes the sub-miniature popular for spying where the object is legibility and not superb photographic quality. At the same time, the "system" type of sub-miniature, when loaded with special fine grain material and used on its proper copying stand can be a surprisingly efficient copying instrument.

Illumination. The illumination must be as uniform as possible over the whole of the area to be copied.

The difficulty in achieving even illumination is due to the fact that the intensity of the light varies according to the law of inverse squares—i.e., at double the distance it is four times weaker, at three times the distance it is nine times weaker, and so on. However, in practice it is always necessary to establish the final details of the lighting set-up by experiment.

If a single lamp is used it should shine as perpendicular as possible on the original. The greater its distance, the more even the illumination. This is however suitable only for dead matt negatives.

The more usual practice is to use at least one lamp from each side. Substantially even illumination results from placing the lamps about one diagonal of the subject apart and at a distance from the subject of about three-quarters of a diagonal. This illumination is satisfactory for most subjects.

More even illumination is given by four lamps arranged over the corners of the copy board. In this case the distance between the lamps and the board may be reduced to a half diagonal of the square containing the subject. This arrangement is the one generally used for copying coloured and continuous tone subjects. It can of course be imitated by making exposures with a single lamp at each of the four corners in turn, or by making two exposures at each side with the two-lamp arrangement.

In all lighting arrangements no direct reflections from the surface should fall on the lens.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

With a focusing screen there is no difficulty in checking the image for the presence of unwanted reflections.

All lamps used for illuminating the copy board should be well diffused. A pearl or opal lamp in a satin finished, matt, or white reflector makes a satisfactory source.

The most uniform lighting is given by tubular strip lighting—i.e., fluorescent lamps. Two such tubes, slightly larger than the long side of the copy and spaced a diagonal apart and at a distance rather less than a diagonal above the long sides of the subject, give a standard of illumination that can be considered uniform for all practical purposes. Fluorescent strip-lighting cannot be used when copying on colour film.

There are certain advantages in using daylight for illuminating the subject—e.g., it is uniform over the whole area. But its strength varies sometimes from moment to moment and it is difficult to make accurate daylight exposures based on test negatives. A convenient arrangement is to have the copy board illuminated by direct daylight under a window, with a mirror placed at the other side to double the light by reflection. Or the copy board may be placed between two windows and illuminated by mirrors at either side.

LAMP DISTANCES FOR COPYING. The distance from lamp to original to be copied must be sufficient to permit even illumination of the whole surface. This depends on the number of lamps used. Top: If one lamp only is available, the original should subtend an angle of not more than 30°. Centre: Two lamps should be placed as ar apart as the diagonal of the original, and three-quarters of the diagonal away from the surface. Bottom: Four lamps can be nearer; and are best spaced half the diagonal from the copying surface.

Negatives and transparencies and other forms of transparent documents are best copied by transmitted light. This type of illumination is also useful for softening the contrast of a hard photographic print and it may be used alone or in combination with reflected light illumination to control the degree of softening. The most convenient method of lighting here is to set the transparency up in front of a sheet of white paper uniformly illuminated by any of the above arrangements. Small subjects like lantern slides can be satisfactorily illuminated by mounting them to fill a cut-out aperture in a piece of card and moving a pearl lamp about behind it for the duration of the exposure. F.P.

Fluorescent Paper Bases. It is nowadays virtually impossible to obtain photographic printing papers suitable for continuous-tone work which do not contain artificial "brightening" agents. These additives absorb ultra-violet radiation in the illumination and re-emit the energy at longer wavelengths within the visible spectrum, so giving the illusion of extra brightness. This re-radiation is not usually distributed evenly over the whole spectrum and so a characteristic tint is given to the base-white, only just detectable by the eye; but readily distinguished by the photographic film.

Though apparently brighter than a normal white, visually, the blue-sensitive materials used so much in Graphic Arts studios will record certain of these additives as darker in tone than a normal white if the radiation is outside the blue region, or much lighter, if the emission is in the shorter wavelengths. Though an unretouched print is easy to copy, any hand-work or air-brushed areas in which process white or greys have been used to modify the photographic image of the print, appear different and may no longer match adjacent image-greys. Even with fluorographic pigments the retoucher cannot precisely judge the actinic effect under the illuminations of different studios.

Short of using printing papers (where available) on non-fluorescing bases, there is only one certain cure. The copyboard of the copying studio must be illuminated by light free from ultra-violet rays. Arcs, discharge lamps or high-efficiency tungsten light-sources need filtering by ultra-violet absorbing glass, or the first negative may be made on an ortho or panchromatic emulsion using low efficiency types of tungsten lamp. Such lamps emit only a very small proportion of ultra-violet rays. And it is the light source that must be filtered, for

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

the fluorescence takes place before the image-forming rays reach the camera lens. J.V.

Lens. Any lens used for copying must have a flat field; the aperture is relatively unimportant. It is desirable to use a lens which has been computed for close subject distances (e.g., anenlarging lens); otherwise poor definition may result, especially with lenses of unsymmetrical design.

One method that may be successful in overcoming such a fault is to reverse the lens in its mount.

Special process lenses, usually apochromatic and of moderate maximum aperture, are used professionally. But they are very expensive and by no means essential for the average copying job for which any good anastigmat lens is quite satisfactory.

Sensitized Material. The average photographer makes copies on odd occasions and wants to see the results right away. So from this point of view alone, sheet film or, possibly, glass plates are the best form of sensitized material. Plates and sheet film are also much easier to handle singly during processing, and a further advantage is the great variety of emulsions available.

One of the most important factors in making a good copy is the correct choice of negative material. The table below gives a very general idea of the most suitable types of emulsion for the principal classes of subject, but considerable variation is possible according to the condition of the original and the type of print required—e.g., the copy may be required to give a true representation of the faded and stained appearance of an old drawing, or it may have to show as nearly as possible what the original looked like when it was new.

FILM AND SUBJECT

Original	*Type of Sensitized Material*	*Filter*
Black and white line drawings; typed or printed matter	Process; ordinary blue-sensitive	None
The same, on age-darkened, yellow or tinted ground	Orthochromatic; panchromatic if ground reddish in character.	Filter as near to ground colour as possible
Black and white photographs and half-tone illustration	Ordinary blue-sensitive; orthochromatic	None
The same on dis-coloured or tinted ground or where image has been toned	Orthochromatic, panchromatic if ground reddish in character.	For discoloured or tinted ground, filter of same colour
Documents to be micro-copied	35 mm. micro-film	Palest yellow that will give sufficient contrast in the print
Coloured originals	Panchromatic	Depends on colours of original; filters should be selected to give good contrast between colours of similar luminosity

The characteristics of the various sensitized materials may also be modified to suit the purpose by the use of filters as indicated.

Exposure. Correct exposure is more important in copying than in many other branches of photography. At the same time, the fact that the subject is normally quite static gives the photographer a chance to experiment.

The only certain way of arriving at the correct exposure for copying an unfamiliar type of original with a temporary lighting set-up is to expose a test negative on the same principle as a test strip is made in enlarging. The simplest arrangement is to advance the edge of a sheet of black card across the subject in successive steps. Another way of using a plate camera is to expose the plate in steps by progressively covering it with the sheath of the plate holder, but extreme care must be taken in this case to prevent the camera from being shaken or moved before the exposure is complete.

The test negatives are developed and fixed, and the best exposure is found by examining the image in white light, or, better still, by making a print. Generally, the correct exposure will be given by the strip on which the white areas of the copy register as a density that will just print out pure white while the deepest tones give the maximum black that the paper can produce. The reproduction of the intermediate tones will depend on the characteristics of the plate—in a print from a process plate, for instance, there will be no intermediate tones between intense black and pure white; a slow, fine-grain panchromatic plate will reproduce a whole range of intermediate greys if they are present in the original.

Processing. The plate must be given exactly the same development as the test negative, preferably in the developer recommended by the plate manufacturer. The experienced professional will generally develop by inspection and be guided solely by the appearance of the image. Anyone unfamiliar with the exact behaviour of the particular plate under his conditions will get on better by following the manufacturer's recommendations and developing by time and temperature.

Line subjects copied on process plates can, if necessary, be cleared by a brief immersion in a ferricyanide reducing bath. This aftertreatment leaves the lines on the negative transparent and free from any trace of fog which would prevent their reproducing as strong black lines on the print.

Printing. Negatives of continuous tone subjects are printed on the most suitable grade of bromide or contact paper in much the same way as ordinary negatives. Line subjects may be printed on the hardest grade of bromide or contact paper, or a more intensely black and white image can be produced by printing on reflex document copying paper. This is very much slower than normal printing papers and

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

is more suitable for contact printing than enlarging. Fine pencil drawings should not, however, be regarded as normal line subjects; excessive contrast can destroy the tone recorded by soft pencil lines or shading.

Scale. The scale of reproduction of a copy is generally of interest—if not of importance—and should be recorded at the time of taking. One of the easiest ways is to mark a scale—e.g., of inches or centimetres—down the margin of the subject, or to lay a ruler alongside. This method enables the scale to be measured directly off any reproduction, either magnified or reduced, that might be made from the copy negative.

The degree of reduction or magnification is determined by the ratio of camera extension to subject distance. That is, for half scale copying, the lens-to-plate distance is half the lens-to-subject distance; for same size they are equal; and for 2× magnification the lens-to-plate distance is twice the lens-to-subject distance. The simple equation is:—

$$M = \frac{v}{u}$$

where M = magnification
v = lens-to-plate distance
u = lens-to-subject distance.

Reduction is the inverse of magnification. That is, a half scale reproduction in terms of magnification is $\frac{1}{2}$, or in terms of reduction 2:—

$$R = \frac{1}{M} = \frac{u}{v}$$

where R = reduction.

To establish the lens-to-subject distance for setting up the camera the equations are:—

$$u = F\left(1 + \frac{1}{M}\right)$$

or

$$u = F(1 + R)$$

where F = the focal length of the lens, or the combination of the camera lens and supplementary lens if used.

In practice the scaling is finally adjusted by measuring the image on the focusing screen. This is because distances should be measured from the nodes of the lens, and these are not precisely known; and further the engraved focal length of a lens is a nominal value and not necessarily an exact one. F.P.

COPYRIGHT AND THE PHOTOGRAPHER

Copyright is a form of property in work; literary, dramatic, musical and artistic work. Ideas, however original, are not protected by the law of copyright. Copyright is an acknowledgement that a person is entitled to the fruit of his own work and the use of his brain in producing that work.

In England the law of copyright is governed by the Copyright Act, 1956. This was a major piece of legislation repealing the Copyright Act of 1911, altering the basis of definition of copyright and providing elaborate transitional provisions where the protection was altered from the position before 1956. The transitional provisions will continue to be of importance for a considerable time yet, but they are highly detailed and in a comment on the present law of copyright in relation to photography such as this, the changes and transitional provisions must be ignored. But quite shortly and oversimplified in statement the change is this: Before 1956 copyright law stressed the rights of the owner in his copyright. Since 1956 the emphasis is upon what he may prevent others doing without his authorizing, i.e. what he may restrain.

Photographs. The Copyright Act, 1956, gives copyright to every "original artistic work" and within the definition of such are photographs. Very broadly the word "artistic" means that some skill or labour has been used. "Photograph" is any product of photography or any process akin to photography (other than a part of a cinematographic film).

In relation to photography, the word "original" probably means "new", i.e., it is a fresh photograph, not a photograph of a photograph. There has been learned discussion as to what "original" means, but the leading legal textbook has narrowed the meaning in relation to photographs to that simple criterion, and the arguments are convincing.

The period of protection is from the date of making the photograph and for fifty years from the end of the calendar year on which the photograph is published. Publication in general terms means that reproductions must be issued to the public. Accordingly photographs have perpetual copyright from the date of being taken until publication, and it is only on publication that the fifty years starts to run.

To enjoy copyright the author must be a person qualified to own the right. The 1956 Act gives in Section 1 a definition of a "qualified person" as follows:—

"For the purposes of any provision of this Act which specifies the conditions under which copyright may subsist in any description of work or other subject-matter, 'qualified person' —(a) in the case of an individual, means a person who is a British subject or British protected person or a citizen of the Republic of Ireland or (not being a British subject or British protected person or a citizen of the Republic of

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Ireland) is domiciled or resident in the United Kingdom or in another country to which that provision extends, and (b) in the case of a body corporate, means a body incorporated under the laws of any part of the United Kingdom or of another country to which that provision extends."

There are also the overriding requirements of common law and policy. For example, there would be no copyright for reasons of public policy in an indecent or obscene photograph. An indecent or obscene nude would probably be recognized as such without difficulty. The law has not defined these aspects. It would be easy to indulge in satire over some decisions but common sense will continue to arbitrate on them.

Ownership of Photographic Copyright. Under the Copyright Act, 1956, it is provided that the author in relation to a photograph means the person who at the time when the photograph is taken is the owner of the material on which it is taken. Prior to 1956 legal authority took the view that a photograph was made when the negative was developed, not from taking the exposure. The provision of the 1956 Act amounts to the same thing but realizes that modern photography does not necessarily involve a negative. Where a photograph is taken on commission, the person who commissioned it is the owner of the copyright with one very important exception; work in the course of employment by a newspaper proprietor (including periodicals) gives the proprietor the first right of publish but thereafter the copyright revests in the author.

The owner of the copyright can prevent any one infringing his rights and in addition claim damages where those rights have been infringed. The remedies are, of course, by way of injunction, damages and for an account.

The owner can also sell his copyright outright by assigning it for a fee. The only legal requirement is that such an assignment must be in writing. Of course he could give it away, but to perfect the gift it would have to be in writing.

Finally, the owner can sell part, i.e., he can grant a licence for a period or for a special purpose. When a copyright owner deals with his rights by assignment or licence, he himself may not reproduce what he has assigned because the assignee, on a valid assignment having been made, becomes the owner of the copyright of what has been assigned.

Dealings in Copyright. The Copyright Act, 1956, also permits an agreement to be made before a work is created whereby the copyright may be vested when it is created in someone other than the author of the work. It can also pass by will or an intestacy. Great care should be taken in framing assignments of copyright so as "not to carry rights in excess of those intended to be assigned". There can be partial assignments of copyright limited as to time or territory or as to the means of or style of reproduction.

Sometimes, of course, an outright assignment is the simplest and most direct method of carrying out the parties' intention. But as a general rule it is far wiser for the owner of copyright to grant a licence. If a publisher becomes the absolute owner of copyright he can use the work as he wishes. In the case of a licence he becomes, if the licence is clearly worded, bound by the terms of the licence. Thus a publisher under licence would not be entitled to publish a work in any different form from that authorized by the licence. Again, if an assignment is made in consideration of a royalty and the copyright is then assigned to a third party, the original owner is not a party to that dealing and could not sue for his royalties. In spite therefore of the disarmingly simple statement that an assignment or exclusive licence needs only the formality of writing any owner of copyright who wishes to dispose of his right, or part of his rights, should ask himself whether or not it might not be wise to obtain professional advice.

Freedom to Take Photographs. The photographer must not infringe another's copyright, and some special dangers outside copyright are dealt with below. But apart from this, he has practically the world and the scene of life from which to create his original artistic work. Within rather obvious limits, he can photograph whatever, wherever and whenever he pleases. He can photograph the Boat Race, or a cricket match, take a snapshot of Charlie Chaplin or the Pope (a snapshot having been described by a learned legal authority as being one of the hazards of using the highway).

Where there are restrictions, they are usually obvious. It would be clearly asking for trouble to take photographs of an atomic plant and a photographer in Russia should be circumspect. But these restrictions are so obvious that they do not need further comment. There are a number of other minor restrictions, e.g., not taking photographs in police courts, which are the subject of special laws or bye-laws, but these restrictions have nothing to do with copyright as such.

Dangers of Infringement. The greatest danger, of course, lies where there is an intention to steal another's work, and this article contains no suggestion of how that may be done with impunity. Copyright is a form of property protecting not ideas, but expression. What is protected is not original thought or information but the original expression of thought or information in some concrete form.

Photography is a relatively narrow mode of expression and limited to its genre. Thus, a photograph of a building does not amount to a breach of the architect's copyright. To infringe the copyright in an architect's building, one would have to build an infringing building. One could infringe plans by photographing them, but that would be an infringement of the plans.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

A photographer may photograph sculpture or artistic craftsmanship if they are permanently situate in public places, for example in streets, squares, and national museums. Possibly statues in a theatre where the public only go by licence after payment would not be a public place.

To constitute an infringement there must be use, directly or indirectly, of the author's work. Two photographs of the same person may be almost identical but have been taken independently without reference to each other. In such a case there could be no infringement; the moral basis of copyright being the eighth commandment: "Thou shalt not steal."

Copies of Letters. Letters perhaps call for special comment, especially as photographers are more and more employed for making copies of letters for business and for legal work.

The writer of a letter is the author and owner of the copyright in the letter. By sending his letter to his addressee, he does not "publish" the letter in the sense in which publishing is used in copyright—unless of course it is a letter to a paper. The letter belongs to the recipient. He commits no offence by throwing it into the fire or selling it, but if he has it copied (and that includes photographing it) there is an infringement of copyright.

Before 1956 it was arguable if photographed correspondence were used in judicial proceedings that there might be a breach of copyright. The Copyright Act 1956, Section 9, expressly provides that there should be no infringement in such a case and the same Section sets out the general exceptions to infringing copyright in artistic work, which, of course, includes photographs. Such exceptions include private study and fair dealing, illustrating again the moral basis of copyright law.

Libellous Photographs. Happily libel is going out of fashion as a speculative and possibly remunerative form of litigation. Before the last war it was otherwise. Everyone can remember striking cases. Thus an unmarried woman whose photograph appeared next door to the picture of a married man and had an unsuitable caption underneath, claimed successfully that her chastity had had doubts cast upon it. Another (a model) claimed damages (and succeeded) because the photographed legs of another girl had been substituted for her own. She protested successfully that a girl of her position in life would not parade her legs like that and that her reputation had suffered.

Some of these cases make intriguing reading to the outsider, but they may well have been painful and distressing to the plaintiff, and one must not forget that everyone is entitled to his or her reputation, a principle guarded jealously over some hundreds of years by our Common Law.

Where models are concerned, a special danger lies. It would be unfortunate if an unmarried woman (unless she had expressly consented) were posed for a maternity scene in the rôle of a mother, or if one used a photograph of a model who was known to be a teetotaller for an advertising campaign to increase the sale of gin. Usually these dangers crop up unintentionally with no blame to anyone. The only safeguard is to insure against such a danger. The premiums are small, and well worth while, to any commercial photographer.

In one case known to the writer, an editor of a well-known publishing house, after insuring continuously for some fifteen years, discontinued his insurance. In the following year a completely innocent libel was published and although the dispute was promptly settled the costs came to much more than the fifteen years' premiums!

So far as models are concerned, it is a frequent practice to have agreements to try to guard against these dangers. The model assigns the copyright, grants unrestricted use of the photograph, and agrees that any reproduction shall be deemed to represent an imaginary person, and that no imputations shall be deemed to be made because the photograph is being used for advertisements and so on. If the model is under legal age, the parent or guardian must also sign the agreement.

Cinema Copyright. A film in the sense of a cinematograph film is, of course, a series of photographs projected so closely together as to give the illusion of movement. The Copyright Act, 1956, granted copyright in a cinematographic film independently of literary or dramatic copyright so that this right does not affect copyright in any literary, dramatic, musical or artistic work from which it is inspired. In order for a cinematographic film to enjoy copyright protection, the maker must have been qualified under the Act to enjoy protection and if it has been published, publication must have been in this country or in a country to which the 1956 Act extends. Publication has a wider meaning than for other work when used in relation to a cinematographic film including sale or hire of the film and offer for sale or hire of copies of the film. It would include, for example, a tape on which the film was recorded. The owner of the copyright in a cinematographic film is the maker, which means the person responsible for making the film. Under the Act, the owner of a copyright in a cinematographic film is also given separate broadcasting and television rights under Section 13 of the Act.

Extent of Copyright Protection. Protection extends far beyond the United Kingdom. The Berne Convention, Berlin, Rome and Brussels Conventions are all highly technical and specialized treaties and there are also reciprocal arrangements within the British Commonwealth.

The large object of these conventions and agreements was to give citizens of the countries who signed the treaties the same rights in other

countries as the natives of those other countries themselves enjoyed. Thus, that a British subject be able to claim in France, or in any other country subscribing to such a treaty, national treatment to protect his copyright in France, or in that other subscribing country. Conversely, that if the owner of copyright in (say) France or some other subscribing country found his rights being infringed in England or a treaty country, that he should be able to claim protection for his copyright not only in France, but in the treaty countries as well.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The United States of America remained outside these Conventions but there were certain American Conventions, the Monte Video Convention, and others, to none of which the United Kingdom was a signatory. These conventions proceeded on the same principle as the ones referred to above, with the same fundamental objective of according national protection to works published in any of the countries who were signatories under the laws of the other contracting states.

Roughly most of the South American countries and the United States of America were parties to these Conventions.

The latest attempt at really internationalizing copyright protection is the Universal Copyright Convention signed at Geneva in 1952. Under this the contracting states agree, broadly speaking, to give the published works of authors in the other contracting countries the same rights as they give to works first published in their own territories. The United States of America ratified the Convention in 1955. Although this Convention was an advance in internationalizing copyright the actual protection afforded by the contracting states is still a matter for the individual state. R.M.H.N.

CORKS. Corks are unsatisfactory as stoppers for bottles of photographic solutions because they deteriorate under the action of many of the ordinary photographic chemicals. Dipping them in hot paraffin wax helps to prevent them from becoming soft and absorbent, but it is safer to use rubber, plastic or glass stoppers.

See also: *Stoppers.*

COROT, JEAN BAPTISTE CAMILLE, 1795–1875. French painter. Executed many clichés-verre, a process "re-invented" by Adalbert Cuvelier and others in 1853, by scratching with an etching needle drawings on glass plates coated with sensitized collodion darkened by exposure to light. The prints were produced on photographic paper by contact copying.

CORRECTION FILTER. Term for any filter which alters colours to suit the colour response of the film in use. Strictly speaking, any colour filter can be regarded as a correction filter, although the term is more commonly applied to filters used in colour photography for adjusting colour temperature. Filters used in this way may be placed over the camera lens or, for indoor work, over the light source.

In professional filming, entire windows are sometimes covered with correction filters when daylight is being used with artificial light colour film; this is often more convenient than blacking-out the windows and using artificial light entirely.

CORREX TANK. Original amateur developing tank for film. The film was attached to a celluloid apron and wound around a reel before immersion in the circular, light-tight developing tank. Raised bosses along the edges of the apron kept the apron and film out of contact and allowed the solution to circulate.

For most purposes the apron tank has now been replaced by the apronless spiral groove type, but for certain special work—e.g., colour processing—in which the wet film is removed from the spool and later returned to it, the apron tank is still preferred because it makes reloading much easier.

See also: *Developing negatives; Tanks.*

CORROSIVE SUBLIMATE. Bleaching agent used in mercury intensification; another name for mercuric chloride.

COSINE LAW. Optical law which formulates the variation of illumination given across the negative by a lens.

When a perfect lens forms an image on a plane at right angles to its optical axis, the image is brightest opposite the centre of the lens. There the lens diameter subtends the greatest angle. At points nearer the edges of the field the lens aperture subtends a narrower angle, and the illuminating beam falls obliquely on the negative. The brightness of the image at such points is therefore less, and the farther away from the centre of the field the point is chosen, the fainter the illumination will be.

According to the cosine law, the illumination varies as the fourth power of the cosine of the semi-angular field measured from the lens axis. (This angle is the angle between the lens axis and an imaginary line from the centre of the lens to the image point in question.)

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The cost of prints is of interest principally to the professional who sells them; his livelihood depends on being able to sell his work at such a price that it will leave him a sufficient margin of profit over his actual expenses in producing it. From the amateur's point of view, the cost of a print must be weighed against the satisfaction he gets out of making it, and that is a purely personal balance sheet.

Anyone who hopes to run a commercial establishment at a profit without knowing exactly what he can afford to charge for his work, is heading for trouble.

Before a commercial photographer knows how much to charge for a job to show a reasonable profit, he must know what it has cost him to produce in both direct and indirect expense—i.e., in wages and materials, and in overheads.

The first essential is a card or sheet for each job. Different studios will have different ideas of how this card should be made up, but the following is a typical specimen.

Job. No. 801

JOB SHEET (FRONT)

Client: Smith & Co., Regent Street, W.1.
Client's Order No. A543

Description of Work:
Photograph of girl brushing hair at dressing table.

Remarks:

Summary:

	£ s. d.	£ s. d.	£ s. d.
Studio costs:			
Wages and salary of proprietor ...	2 0 0		
Materials	10 0		
		2 10 0	
Add on cost at 71 per cent		1 15 6	
		4 5 6	
Add profit at 100 per cent		2 10 0	
			6 15 6
Outside work ...		6 6 6	
Add profit		2 2 2	
			8 8 8
Total			15 4 2
Charge			15 15 0

JOB SHEET (BACK)
STUDIO WORK
Wages

Date	Artist	Hours	Rate £ s. d.	Amount £ s. d.
May 12th, 1962 ...	Brown	2	7 0	14 0
May 13th, 1962 ...	Brown	1	7 0	7 0
May 13th, 1962 ...	Jones	2	6 6	13 0
May 13th, 1962 ...	Jones, K.	1	6 0	6 0
				2 0 0

MATERIAL

Description	Amount £ s. d.	£ s. d.
4 plates ...	2 0	8 0
6 sheets ...		2 0
		10 0

OUTSIDE WORK AND SPECIAL ITEMS

Invoice No.	Supplier	Description	Amount £ s. d.
600	Black and Co.	Hire of table	1 13 6
1	Miss Smith	Model fee	3 3 0
601	Furniture Co.	Hire of props	1 10 0
			6 6 6

The client's name and a brief description of the job are entered in the job sheet. Each job is numbered and the sheet is given the corresponding number. It follows the job through, and each individual concerned enters the time spent on taking the photograph, developing, retouching, negative printing, print finishing, etc. Details of the film, paper, flash bulbs, etc., used are also entered on it. Travelling time and waiting time, if any, and hotel and travelling expenses must be entered. If a car is used it may be charged up at so much a mile to include petrol, oil, depreciation, repairs, etc.

The cost of any outside work, hire of properties and model fees are included, in fact, all the expenses which can be definitely earmarked to the job. These expenses are what accountants term "direct expenses". The proprietor's operating wage and the employees' wages are broken down to an hourly rate in working out the cost of the labour on the job. The job sheet now shows all the direct expenses in connexion with the job.

A percentage may be added to the cost of materials to allow for waste and a percentage to the labour costs to cover lost or idle time.

To help in arriving at labour costs it may be preferred for each employee to keep a time sheet, a typical example of which is shown.

TIME SHEET

Name ..... *Week ended* .....

Day	Description	Job. No.	Hours	Rate	£ s. d.
Monday ...					
Tuesday ...					
Wednesday					
Thursday ...					
Friday ...					
Saturday ...					

A little more work will be involved in keeping and analysing time sheets, but they have the advantage that the job sheet need not follow the jobs round with the risk of getting mislaid or soiled. The information on these time sheets will be summarized weekly in the office and the result entered on a job sheet.

A Materials Used Sheet and an Expenses Sheet should also be completed for each job. Suitable printed sheets can be obtained from most stationers.

Overheads. Such items as rent, lighting, office expenses, stationery, depreciation, etc., are generally known collectively as overheads.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The figure for these is found in the annual accounts. Here is a specimen profit and loss account of a commercial photographer.

PROFIT AND LOSS ACCOUNT
Commercial Photographer

	£
Sales	8,000
Materials Consumed	700
Wages	1,500
Wages, proprietor (as photographer)	800
Outside work, including model fees, property hire, etc.	300
Travelling and hotel expenses, including car expenses	350
	3,650
Gross profit	4,350
Expenses (Overheads):	
Trade and office sundries	120
Printing and stationery	150
Post and carriage	75
Advertising	150
Office salaries	300
Rent and rates	450
Heating and lighting	100
Telephone	70
Insurance	30
Depreciation	75
Repairs and renewals	50
Accountancy	30
Bad debts	30
Proprietor's salary (as administrator) ...	500
	2,130
Net profit	2,220

This shows overheads, or on-costs, as they are frequently called, as £2,130. Now each job has got to bear its proper proportion of these overheads. The wages, including the proprietor's wages, or wages and materials, are generally a guide to the relative size of the job, so the most common method is to apply the overheads in proportion to the wages and materials. It will be noted that the proprietor's earnings fall under three headings: first as a photographer, then as an administrator and finally in the profits.

From the specimen profit and loss accounts, it will be seen that the overhead expenses at £2,130 are equivalent to 71 per cent of the £3,000 paid out for wages and materials. So to absorb the overheads into the costs there must be included by way of overheads a figure equivalent to 71 per cent of the wages and materials of each job.

Having got the amount of wages and materials which gives the prime costs; having a note of the outside work and any special expenses, and having included overheads by adding in the amount equivalent to 71 per cent of the wages and materials, the total represents the total cost of the job, including overheads.

Percentage of Profit. If a price has been quoted for the job, the difference between the price and the cost determines the profit (or loss), and the summary on the cost sheet is completed by inserting the amount to be charged and the profit which is accordingly made.

If a price is yet to be given, then the price is arrived at by adding the profit to the costs. The figure should certainly not be less than 50 per cent for an ordinary mechanical job and may run up to several hundred per cent if much creative work has been put into it, as is frequently the case in some forms of advertisement illustration.

The total cost and profit added together, make the price to be charged.

In most studios the waste of material is not sufficiently important to worry about, but if it is considered necessary to deal with such items they can best be taken into account by way of a percentage on the wages and the materials. The percentages can only be estimated by the individual photographer in the light of his experience. For example—admittedly a severe one—if an assistant can only be found employment for half the normal working hours the charge made for that part of a job constituting his services must be at double the rate he is actualiy paid.

Financial Account. Finally to prove if the costing has been accurate, the aggregate of the cost figures must be reconciled with the corresponding figures in the financial accounts. This is achieved by summarizing the costs and the profits on all the jobs to give yearly totals.

The totals of wages, materials, outside and special expenses, on-cost, profit and sales respectively can be compared with the corresponding items in the financial accounts. To obtain the comparison with the total of on-cost it will, of course, be necessary to total the overheads in the financial accounts that the percentage was intended to cover. Theoretically an exact match should result. In practice it seldom does.

If the comparison throws up serious discrepancies it should be possible to find out the reason. If, for example, the total of the wages taken up in the jobs costs is less than the actual year's wages bill it could be accounted for by lost time. This could be confirmed by the analysis of the wages sheets. It should be possible to check through if there is any discrepancy on outside work and special expenses. A discrepancy in the on-cost would probably be explained by the percentage worked on being too low or too high. It would, therefore, call for revision in the future. This running summary of job results also shows the profits to any given moment.

Simplified Method. There is a simplified method by which the small commercial studio, particularly the one-man business, can charge out its work or check its price list.

It is necessary first of all to arrive at the total cost of running the studio. This cost will include the salary that the photographer has fixed for himself, the wages of any assistants, all overheads such as rent, lighting, heating, telephone, advertising, printing and stationery and trade and office expenses (but eliminating

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

materials and special expenses such as model fees, hotel and travelling expenses). These figures can, of course, be ascertained from the annual accounts. Allowing for a weekly half-day, Sundays, Bank Holidays and a fortnight's vacation, there are 271 working days. On the basis of an eight-hour day this gives 2,168 working hours in a year. This should be reduced by at least a third to allow for unproductive time, such as office work, which gives 1,445 or, say 1,400 productive hours. The total studio costs divided by 1,400 will give cost per productive hour. The number of hours spent on the job, multiplied by this hourly rate, plus the cost of material used, and any special expenses will give the cost of the job. Only the proprietor's hours should be taken into consideration. The time of the assistant should be ignored.

The rate of profit will be governed by circumstances (such circumstances have already been discussed earlier). When the profit has been added the resulting total will be the calculated charge for the job, which will enable the photographer to fix his price.

Book: *The Business of Photography*, by C. Abel (London).

COUPLER. Chemical used in colour development where it combines with certain by-products of the development process to form a dye.

Modern colour photographs are almost entirely made on subtractive materials in which the dyes that form the coloured images are synthesized in the photographic emulsion layers during development. Where exposed silver halide is being reduced to silver, the developer becomes oxidized. The oxidized developer molecules in certain cases, e.g. phenylene diamines, have the property of combining, or "coupling" with other special compounds to form dyes. Thus an image of dye is built-up at the same time as the silver image.

These special compounds are called couplers, and three different types are used to form the yellow, magenta and cyan images. For example, derivatives of phenol or naphthol are commonly used to form cyan dyes, pyrazolones for magenta, and aceto-acetanilides for yellow colours. If the couplers are of simple constitution, and fairly soluble, they can be dissolved in developers. Each film layer is then colour-developed individually with a different developer-coupler combination.

When the couplers are incorporated in the emulsion layers during manufacture, one developer produces all three dye images. However, the coupler solubility must be reduced, otherwise the couplers could wander into the wrong layer and degrade the colours. More complex molecules have been devised for this purpose; they are dispersed in the emulsion layers either as colloidal suspensions, or dissolved in minute oily droplets. In either case, their water solubility is low, so that no wandering occurs. Considerable research has been required to design couplers which react at the appropriate rate and form dyes of the correct colour and stability.

TYPICAL COUPLER REACTION: Top: *The silver halide and developer react producing metallic silver and oxidized developer complexes.* Bottom: *The oxidized developer reacts with the coupler in the emulsion (or in the processing solution) to form dye.*

Coloured Couplers. Most coupler substances are colourless until they form the dye image with the development product. But there are reasons why a coupler that is already coloured may be desirable.

The basis of colour photography is the fact that white light is made up of three broad regions of the spectrum—blue, green and red. Theoretically the three dyes that form the image in a modern colour negative material each control one of these sections. Thus the yellow dye controls the amount of blue light transmitted by the negative, magenta controls green and cyan controls the red light. If the dyes were perfect, they would do this and nothing more. Thus for example, if the magenta image could be obtained on its own and viewed through a green filter, the image would be seen. But the dye should be transparent to blue and red light, so that if we looked at it through blue or red filters, we should see no image. In fact we would see a faint image through these filters because the dye is imperfect and is absorbing a certain proportion of colours other than green. These unwanted absorptions will mean that at the next stage, printing on to the colour positive, the magenta negative will not only print on to the green sensitive layer of the positive, but on to the other two layers as well. Thus it is impossible to obtain pure colours in the positive because there is interference from these unwanted absorptions.

An elegant way of overcoming this difficulty is based on the following consideration. If we still take the magenta image on the negative as our example, and view it through a blue filter, we see a low contrast image. If the layer was coloured pale yellow and the yellow colour destroyed in exact proportion as the magenta dye is formed, we should see nothing but a uniform density. At every point on the negative,

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

the sum of the blue absorption of the magenta dye formed and the yellow dye remaining would be the same. The image would thus appear to be formed from a "perfect" dye, and would not print in the wrong places on the positive.

In practice this can be achieved by using coloured couplers. The couplers themselves are in fact dyes, and when they react with the oxidized colour developer, the dye molecules are destroyed, coupling takes place, and a new dye of a different colour is formed.

Theoretically all six unwanted absorptions—two colours for each of the three dyes—could be corrected by suitable coloured couplers. In fact it is found that yellow dyes are usually good enough without correction, magenta dyes need correction for unwanted blue absorption, while cyan dyes absorb too much of both the green and the blue. Thus magenta *couplers* that absorb blue light—i.e. are themselves yellow—are required, and the cyan couplers used absorb blue and green, i.e. are orange-red in colour. This accounts for the overall strong yellow-orange tint of many modern colour negative materials. This overall colour of course increases the amount of light required for printing, particularly the amount of blue light, and printing times or printing light output must be increased. This is a small price to pay for the considerable improvement in the saturation of the colours that result.

This type of more or less automatic colour correction corresponds to masking as used with colour separation negatives.

Similar effects can be obtained by a coupler which is colourless to start with, but where *unused* coupler left over after the formation of the dye image is turned into a masking dye at a later stage of the process. J.Mo.

COVERING POWER. Term mainly applied to optical coverage of lenses, but can also refer to the light-obscuring ability of a silver image.

Lenses. The covering power of a lens refers to the maximum area of the focal plane over which the lens is capable of giving an evenly illuminated image of an acceptable standard of definition.

The limits of the area usefully covered are reached when either the definition or the illumination fall below the required standard. It also depends on the angle of view of the lens.

Definition. Aberrations tend to increase away from the axis of the lens so that, from one cause or another, the definition of the image falls off suddenly beyond a certain distance from the optical axis. For the same lens, the falling off occurs earlier at wide apertures—i.e., the covering power is greatest when the lens is stopped down.

Illumination. When a uniformly bright object plane is focused by the lens on the plane of the negative in a camera, the illumination of the

COVERING POWER. Relative image brightness (taking 100 per cent as the brightness in the centre of the negative) is here plotted against the distance in degrees from the centre of the field. The top dotted curve corresponds to the theoretical $\cos^4\theta$ relationship, the other curves show actual falling off in brightness at a small, a medium, and full aperture respectively.

negative is no longer uniform but falls off steadily from centre to edge.

Four effects contribute to this reduction in illumination. The first three operate whatever the lens type and whatever the relative aperture and together reduce the illumination by a factor $\cos^4\theta$, where θ is the semi-angle of view. The fourth effect is known as vignetting, and depends on the type of lens construction, generally decreasing to zero as the lens is stopped down.

(1) Marginal areas of the uniformly bright object are farther from the lens than the central area, and the lens receives less light from them in accordance with the inverse square law; the corresponding areas in the negative are therefore less brightly illuminated. The reduction in illumination is proportional to $\cos^2\theta$.

(2) For two object areas of the same size, one on the axis and one near the margin, the latter is inclined at an angle θ to the line joining it to the centre of the lens. In other words, a given cone of rays is spread over a bigger area than the central cone at right angles to the subject plane. The light reflected in the direction of the lens from such a marginal area is reduced by a factor $\cos\theta$ compared with the light reflected towards the lens from an area on the lens axis (Lambert's law).

(3) The effective aperture of the lens is reduced when viewed obliquely, appearing as an ellipse. A marginal area of the negative therefore receives less light than a central area. Again, the effective aperture and the corresponding illumination is reduced by a factor $\cos\theta$.

(4) With complicated lens types an oblique beam of light may be partly cut off by the mount. This may be caused by some obstructing metalwork, but more frequently it is due to the fact that lens elements some distance

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

VIGNETTING: A deep lens mount may cut off marginal rays of light, thus reducing the image brightness near the corners of the negative. This effect occurs in addition to the falling off in illumination at the edge of the field due to the obliqueness of the rays reaching the negative. A shallower mount and large front lens element improve both shortcomings.

from the iris diaphragm are too small in diameter. The effect is known as vignetting, and causes a reduction in marginal illumination. This reduction in effective aperture is additional to the obliquity factor (3) above. Vignetting should not be serious with lenses covering moderate angles, but is often appreciable in wide-angle lenses. It decreases as the lens is stopped down.

Apart from vignetting, the reduction in marginal illumination due to what may be called photometric causes—the $\cos^4\theta$ relation—becomes serious only for wide-angle lenses. For lenses covering a moderate angle of 50° ($\theta = 25°$) the value of $\cos^4\theta$ is 0·68. the corresponding reduction in illumination being 32 per cent.

A reduction of about 20 per cent in the illumination of the margins of the image plane is not appreciable, so that the defect goes unnoticed in normal and narrow-angle lenses.

The effect is much more serious in wide-angle lenses, but as vignetting becomes less as the lens is stopped down it may not be usually obvious in lenses that work at a small aperture.

In extreme wide-angle lenses, however, the effect is so marked that it is necessary to reduce the central illumination with an opaque diaphragm. This is sometimes made in the form of a metal star that can be rotated during exposure by blowing on it.

Angle of View. The closer the plate is brought to the lens—i.e., the greater the distance of the object focused—the greater the angle subtended by the diagonal of the plate at the lens. This means that the maximum covering power is required when the lens is focused on infinity. As the lens is moved away from the plate to focus objects closer than infinity, the angle of view becomes smaller and the covering power required is correspondingly less.

In the same way, a long-focus lens can do with a relatively lower covering power than a normal lens for a given negative size, while a wide-angle lens needs a relatively greater covering power.

For most practical purposes, a lens should cover a negative of diagonal equal to its own focal length. Where the camera is equipped with movements, it must have a lens of greater covering power than this or the use of any of the movements will take part of the plate outside the limits of the field. The general practice is to use a lens of slightly longer focal length than the one normally specified for the negative size—i.e., for a quarter plate camera fitted with movements, a lens would be used which would comfortably cover a 4 × 5 ins. plate. K.J.H.

Covering Power of Image Silver. The weight of silver, expressed in grams per square decimeter of image area, that is required per unit of density is referred to as the photometric constant or equivalent and is a measure of the light obscuring, or covering power of the silver pigment.

The covering power changes with the size of the developed grain and to some extent with the density at which it is measured. A large grain can be regarded as stopping light in direct proportion to its projected area just as any opaque macroscopic body casts a shadow.

The grains of a developed emulsion, even if having a filamentary fine-structure, may be considered as being roughly spherical. On account of the less advantageous ratio of area to volume the larger grains will utilize silver less efficiently as a pigment. Grains of 0·5 micron diameter need about 0·01 grams of silver per square decimeter for a unit density whereas grains of 1·5 microns diameter require about three times as much.

Very small grains of diameter less than 0·05 microns behave as though their optical diameter is greater than their mechanical diameter and the covering power of images formed from these small grains can be such that only 0·002 gram of silver is required per square decimeter to give a unit density.

Physically-developed images are more compact in their fine-structure than are chemically developed ones. The above observations hold for very fine physically-developed particles, but the physically-developed images of larger particles appear grey and are of comparatively poor covering power because of the higher conductivity and reflectivity of the more massive silver.

CREDIT. Printed acknowledgment of the origin of a photograph reproduced in a publication. Photographs may be credited to the photographer and/or the agency who distributes them and/or some third party who may have acquired all the rights in them. Policy varies from publication to publication, some never giving credit, others always doing so, and yet others crediting only those photographers whose names are already well known. Many newspapers have, in recent years, begun giving credit to their own staff men.

Agencies specializing in news photographs claim as a rule exclusive credit; whilst agencies dealing with general or pictorial subjects mostly ask for photographs to be credited jointly to the photographer and themselves. If their

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

names have a readily recognizable commercial character there is no reason to object to this practice, but if they trade under some personal name there are obvious disadvantages to the photographer.

Advertising agents and their clients, who have commissioned photographs and so acquired some rights in them, usually try to obtain a credit whenever the photographer has an additional chance of publishing the prints in question. This tendency is human but regrettable. Experienced publishers recognize these demands as requests for unpaid advertising and generally offer to provide either a credit or a reproduction fee, but not both.

The photographer cannot expect to receive a credit unless he takes the trouble to see that his name is either on or at least clearly associated with the photograph. The best method of ensuring this is to use a rubber stamp on the back of the print. Its text should preferably be confined to the photographer's name, address and telephone number. Some photographers go to great pains to include elaborate references to their rights and conditions of reproduction, but such admonitions are unnecessary.

It is wise to stamp on to one's prints the words "please credit . . .", or something similar, but the practice of permitting publication of pictures for credit instead of payment is to be strongly discouraged.

CRIME PHOTOGRAPHY

Photography is used by the police to provide evidence and supplement written reports on a very extensive scale. Much of this work is of a routine character and not connected with the actual investigation of crime. The equipment and techniques employed in this branch are those of normal photography. Most of such photography is done "in the field".

Apart from such general work, however, there is the highly specialized field of photography applied to crime detection. Much of this is carried on in the laboratory with special equipment and techniques. By the use of such technical aids as infra-red and ultra-violet lighting, and radiography, in conjunction with suitable filters and sensitized materials, criminal evidence that would otherwise remain hidden can often be brought to light.

The work of the laboratory carries on from where the outdoor photographer leaves off, so there is inevitably a certain amount of overlapping in the work of the two departments.

In presenting photographs as evidence, the pictures must not be retouched—or even spotted—in any way.

Equipment. For ordinary police work the official photographer uses a 4¾ × 6½ ins. camera, with an 8 ins. lens and a wide-angle lens of about 4¼ ins. in reserve. He probably carries a comprehensive range of filters for both general and specialized effects.

For lighting subjects in and out of doors he will have a supply of enclosed flash bulbs with, possibly, several high intensity Photoflood bulbs, reflectors and flexible leads and plugs. The special circumstances of this type of photography may call for fast, medium or slow orthochromatic or panchromatic films or plates.

In the police laboratory, the photographic equipment normally includes a long extension camera which can be fitted with short focus camera lenses to make low power photomicrographs up to about ten diameters. For greater magnification than this, the photographer may use any of the normal equipment for photomicrography. Finally, in addition to the usual lighting equipment—Photofloods, flash bulbs, and normal electric lighting units—there are special lamps for generating infra-red and ultra-violet light.

The infra-red light sources are used for such work as the examination of heavily dyed textile fibres, of sections of biological material where the natural pigment is reddish or brownish in colour, and for showing up the presence of carbon on sections taken from the lung in cases of suffocation by smoke. Various inks, sealing waxes, seals, markings of stamps, etc., often yield positive evidence by the use of infra-red photomicrography. Ultra-violet lighting is extensively used for revealing forgeries and fakes. Many inks and pigments which are apparently identical by ordinary lighting fluoresce differently under ultra-violet lighting, and the difference can be photographed.

There is rarely any provision for making X-rays in the photographic department: when X-rays are required the work is done by independent specialist firms.

Routine Work. The ordinary police photographic department staffed by policemen photographers is concerned almost entirely with straightforward pictures of scenes of crime and personal identification. This makes up the overwhelming majority of photographic jobs in crime photography.

The Scene of the Crime. A typical outdoor job for the police photographer might be to take a number of exterior scenes of a house showing the point of entry of a criminal, of a field, wood or lane connected with a murder or sex offence, or a road showing the scene of an accident. Photographs are wanted here to show how the particular spot was approached, its visibility from the highway and its connexion with other points of evidence.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

If the crime has been committed in a building it is usual to take several general views from different angles, using a wide angle lens in conjunction with Photoflood or flash bulbs, or using daylight, with or without artificial light of some sort, as illumination. Special attention is paid to recording the position of various objects with relation to the body (if there is one), the point of entry or exit of any intruder, etc. Care has to be taken when using the wide angle lens to avoid distortion caused by having the back of the camera out of vertical.

Close-ups of important details are generally desirable. For these and the more general shots the proprietary self-contained lighting units are very valuable. They not only ensure adequate and correct illumination, but also allow the operator the opportunity, which he does not get with flash, of examining the picture before exposure. This allows him to avoid "flares" and reflections from mirrors, polished fittings, glass, etc., in the final picture. Backed plates are normally preferable for interior work since they yield brighter and clearer negatives.

The use of available daylight brings in a number of minor complications, since its uncertain and fluctuating intensity and the often unsuitable position of windows make calculations of exposure rather rough and ready and may render it difficult to take an exposure in the direction required. These difficulties are overcome by obscuring windows with curtains and using artificial illumination only. On occasions this may be supplied by flash bulbs or powder.

In the latter case the lens is focused on an ordinary hand torch directed towards the camera from each side of the subject in turn. This also helps to define the limits of the picture.

Hans Gross, the authority on criminal investigation, lays down as an inviolable rule that one must " never alter the position of, or pick up, or even touch any object before it has been minutely described in the report". The value of the camera to make a record of the position of objects in relation to each other and to reproduce a likeness of an object, as it was when first found, thus becomes very obvious indeed.

Generally, the photographs considered essential are those showing the scene itself, any points of exit and entry, all points where traces of the crime are found or where they might have been expected but where, in fact, there are none, and the scene from spots where witnesses have seen, or could have seen, anything. A number of these points are often not apparent in the early stages of the investigation so that it is generally considered better to take too many rather than too few photographs. Views are, therefore, taken from several sides and angles, and reference points from which the photographs were taken are marked on a diagram of the scene. The diagram is also marked with measurements showing the space-relationship of various objects.

The photographs, beside being an impartial record of things present in their state when photographed, will also indicate things which should normally be there but are in fact absent. Sometimes such missing elements may lead to important deductions being made as to how, or by whom, the crime was committed.

Road Accidents. In road accident cases, photographs are taken along the lines of approach of the two vehicles at the eye height of the sitting drivers in order to demonstrate their field of vision before the accident. Photographs are also taken of the actual scene and of any marks on the cars which may have special significance. There may be skid marks on the road, or, in the case of hit-and-run incidents, tyre impressions on the victim's person. How these are photographed will depend upon the nature of the surface and the type of impression. A polaroid screen may be used over the lens to reduce reflection from the road. Or again, the photographer may actually make use of the glare caused by oblique daylight to obtain better contrast, taking vertical photographs of the surface with the camera stopped down to less than *f*11, and a process film to give extreme contrast. If it is visible, the whole tyre impression is recorded in the hope that, besides identifying the make of tyre, the particular tyre in question may show a characteristic marking or fault such as a peculiar cut, mark, etc.

Identification. Photographs for identification are taken in a studio with light-coloured walls. Profile and full face photos of one-eighth scale, and full length photos of 1/27th scale are taken on the fastest type of plate or film, with the lens at about the level of the sitter's face or chest height for the full length photograph. The focal length of the lens used is at least equal to the diameter of the picture in order to produce satisfactory perspective free from distortion of the features.

When recording diseased skin, bruises or injuries, use may be made of suitable filters and plates to obtain either faithful or deliberately exaggerated reproduction. By using an orthochromatic plate and no filter under artificial lighting, for instance, it is possible to show the extent of bruises not readily visible to the eye. They can be made even plainer by the use of colour-insensitive plates.

"Candid" motion pictures are a valuable means of identification. Pictures taken of a man "off his guard" often reveal characteristic movements of hands, feet or head which can identify him as surely as a physical peculiarity. X-ray photographs of teeth and other portions of the anatomy, preserved in practitioners' records, have, on occasions, been produced for positive identification of living people and even

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

more particularly for identifying cadavers.

Identification after Death. It is possible to identify corpses even in such a state of advanced decomposition that the features are unrecognizable. For this the police need a photograph of the person when alive, for preference one of the full face. A life-size negative of the skull of the corpse is taken from the same angle as the existing photograph, and printed as a transparency. The existing photograph is then enlarged to life size and placed under the transparency and in register with it. The extent to which the eyes, ears and nose in the "living" photograph correspond to the sockets, the bony aperture and the nasal bones, respectively, in the transparency of the skull is noted. These observations will go a long way towards establishing whether the two photographs belong to one and the same person. If "living" photographs of the head in three different positions are available, the certainty of identification can be almost guaranteed.

Dusts. High power photomicrography of occupational dusts—i.e., fragments of material found in a place where a man works—has often proved of importance in identification, or in connecting suspects with a crime.

Coal particles can be embedded in the skin of miners and remain for a number of years; certain classes of quarrymen are found to have tiny particles of silica in their breathing tracts and lungs. The presence of shellac in the system has been used to identify the body of a french polisher. Similarly, metal particles are associated with engineers, cereal and malt debris with brewery workers, and flour and starches with adhesive makers, bakers, millers, etc. There are many similar associations.

Finger Prints. The pattern of the ridges on the finger tips is an unchanging characteristic of the individual. These ridges contain sweat glands, and pressure of the finger tip on a surface leaves an extremely fine film of grease in the characteristic pattern of the ridges. When the finger prints are dusted with an appropriate powder, the powder clings to the greasy parts and can be blown away from the rest of the area, leaving a finger print impression that is visible and can be photographed.

Suitably coloured dusting powders are used to contrast with the colour of the surfaces bearing the finger prints. Black powder is used for a white ground, white powder for a black ground. On coloured grounds, a coloured powder is used in conjunction with the plates and colour filters that give the best contrast. On multi-coloured backgrounds the photographer uses a powder which fluoresces in ultra-violet light to give a photograph in which the glowing finger prints are shown against a dull background.

The photographer's ingenuity is demonstrated at its best when finger prints occur in different places, for example, on both sides of a piece of glass. In this case the prints on one side are dusted with a light powder and photographed against a dark background, after which the prints on the reverse side are dusted with a black powder and photographed against a white background.

Prints in an inaccessible position may often be photographed by employing a mirror. In this case unbacked film loaded the wrong way round in the holder is used to counteract the reversal of the image by the mirror.

The police record finger prints by pressing the fingers first on to an inked pad and then on to a sheet of white paper, so that the ridges show as black lines on a white background—the reverse of the picture produced when white powdered or light-coloured powdered finger prints are photographed against a dark background. For this reason the tones of the photograph must be reversed, but it must not be reversed laterally—i.e., from left to right. To do this a lateral reverse negative is prepared by taking a photograph on an unbacked plate or film, loaded back to front in the camera. From this an intermediate positive transparency is prepared. The positive is then printed in the usual way to obtain prints for comparison with the actual police records, the effect being that of a finger print made with black ink on white paper. For finger prints consisting of dark coloured powder on a light background, a direct photographic method without reversal gives the required print for comparison.

There is a simpler method of correctly recording light powder finger prints on a dark ground. If the plate holder is loaded with bromide paper and the finger prints are photographed through a prism or optical mirror set up in front of the lens to correct the lateral reversal, developing and fixing in the usual way gives the desired print. But by this method only one print can be made for each exposure in the camera and any duplicate records must be made by repeating the whole process.

Another method preferred by a number of police departments for photographing light powder impressions is to expose on a thin fast film, and then develop, bleach, expose to white light, and redevelop. This gives a positive which can be printed in the normal way to give a black on white image with no lateral reversal.

For comparing finger print photographs, enlargements of about 6 diameters are used.

The skin on the finger tips of corpses is often hard and shrivelled, making straightforward finger printing impossible. In such cases, the skin is stripped from the fingers, well massaged with a barium paste, mounted between glass plates and photographed with rear illumination and the lens stopped down to at least *f* 45.

Foot Prints. Police photography also includes an appreciable amount of foot print recording either in the form of dust prints on linoleum, etc., or impressions in earth, clay, or snow.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Examination of car tyre marks also comes into this category.

Technically the photography is fairly straightforward. Oblique illumination is often used where practicable to show up impressions in relief.

Debris on the Person. Photomicrography at magnifications of the order of 200× to 750× is employed for the examination of fibres from clothing and other textiles, paper, hairs, dust and debris, which may be found in the turn-ups of trousers, in pockets, under the finger nails, and in the aural or nasal cavities.

In many instances the debris under the nails or in the turn-ups of the trousers has been obviously connected with the scene of a crime—e.g., fragments of pine needles have been found in the clothing of the murderer when the crime took place in a wood, and alum and wood fragments have been photographed on the clothing of a thief who had ripped open the fireproof lining of a safe.

Debris in Lungs. The lungs of a corpse often reveal significant traces of foreign matter that help in establishing the cause and time of death, and even of identity (when they contain characteristic occupational dusts). Thus in the examination of the lungs of a man who had died in a fire, sections of the lung tissue stained red with safranin and photographed through a red filter on panchromatic film clearly showed carbon deposits in the tissue. These deposits indicated that the man had inhaled smoke from the fire and therefore was alive before the fire had started.

The debris in the water of ponds, ditches, and streams is often characteristic, and, in the case of drowning, the water in the lungs should contain debris of a similar nature to that in the water in which it is presumed death occurred. Totally different debris present could indicate that the body had been taken away from the site of death, and put into the water in another place to divert suspicion and enquiries from the proper quarter. Debris present in the lungs, therefore, allows the real site of death to be sought and identified with accuracy.

Stains on Clothing. Bloodstains are such a vital form of evidence that many complex techniques have been developed to detect them on all types of surface and material. Photography in one form or another enters into all these methods of detection since a photograph is more convincing than a mere statement. But in many instances the evidence could not be revealed without the photographic process.

For instance, a coloured fabric may be more transparent to infra-red rays than a bloodstain of the same colour. Or the stain may have been caught in such a state that it is relatively opaque to the rays. In these circumstances the presence of otherwise invisible stains, their shape, and location, can be reproduced by infra-red photographic technique.

Blood, seminal stains, starches and occupational dusts of various types are also revealed by photomicrography which shows up the characteristic structure and colour of the material; and by ultra-violet radiation which characterizes certain substances by their fluorescence. Alternatively, infra-red illumination may be used, in particular to reveal internal structural detail normally masked by a skin or covering that is relatively opaque to visible light.

Poisons. In poisoning cases, particularly in tropical countries, the presence of certain vegetable poisons may sometimes be established by the presence of characteristic fragments of berries, leaves, stems or roots. Photomicrographs of such fragments assist the prosecution in explaining to the judge and jury reasons for identifying the material as the vegetable poison used. Various dried and ground insects, powdered glass, and finely chopped hair are other fairly common native poisons whose presence can be clearly shown in photomicrographs.

Firearms and Ammunition. Guns and bullets can usually be identified by the striations left on the bullets by the rifling of the weapon, the indentation left by the firing pin in the soft metal of the firing cap, the impression made on the base of the cartridge by being forced into contact with the gun breach by the pressure of the explosion, and the marks of the extractor and the ejector on the cartridges. Evidence of this type is photographed generally at magnifications of about 3× to 6× on slow or medium speed emulsions giving good or high contrast. The lighting is arranged to shine almost parallel to the surface so that it throws the indentation, scratches, etc., into bold relief. (This method is also used for examining markings on metal objects like coins, in forgery cases, and door locks, window hasps, etc., in "breaking and entering" cases).

Textiles may be examined for stains and powder marks from bullets, etc., under infra-red light. The opaque carbon from the explosive blown from the muzzle of the firearm is deposited around the point of impact of the bullet according to certain well-known laws.

For instance, if these marks can be seen, as on a white fabric, it is possible to calculate the distance, etc., of the muzzle from the fabric at the time of firing. With coloured fabrics, the location of this carbon deposit is not so easy to see, but when photographed by infra-red light the conformation of the carbon deposit can be clearly demonstrated, even on dark coloured textiles. Where the bullet enters the body it generally leaves a ring of metal which can be seen in an X-ray photograph where the metal, being relatively opaque to the X-rays, shows up as a distinct image.

Documents. Documents on which the writing has been obliterated by dirt or by the passage of time are regularly photographed by infra-red illumination to reveal the original writing. This is possible because infra-red light generally

CC-0. Agamnigam Digital Preservation Foundation of Chandigarh

shows a higher penetrating power than visual light, and although it is invisible, infra-red light affects the emulsion of the special plates and produces a visible photographic image. Sometimes even charred documents can be made legible by this method provided the charring hasn't gone too far.

The same technique has also revealed alterations in passports, additions in different ink or with different pencil to documents, and it has often been successful in reproducing indecipherable drawings and sketches which have been obliterated by rubbing or other mechanical friction.

Since some inks are more opaque than others to infra-red rays, it has been possible to reproduce the hidden text in certain passages of old manuscripts which have been obliterated—e.g. by the censor of the Spanish Inquisition. More recently the method has been used to reveal the original document when dirt, inks, etc., have been deliberately applied in an endeavour to hide the underlying text.

Writing. Questions of the authorship of handwriting are tackled by comparing low power photomicrographs of specimens. Negatives of individual letters enlarged from five to ten times can be superimposed to show similarities. The same type of test is used to establish typewritten text as the work of one particular machine. No two typewriters give identical impressions; there are always slight differences in the lining up of the type bars or even microscopic differences in the shape of the letters. All these points can be demonstrated with photographically enlarged reproductions. Photography by oblique light can also reveal the impression left on a pad after the top sheet with the writing on it has been torn off.

Colour Photography. Most laboratories are making increasing use of colour photography and photomicrography to make the point of their pictures clearer. In the U.S.A. a portable back-projector is sometimes taken into court to show colour transparencies on it. J.A.R.

CRITICAL ANGLE. When a ray travels from a denser to a rarer medium it is refracted away from the normal: the angle of incidence at which the emergent ray just grazes the surface is the critical angle. For all greater angles of incidence most of the light will be reflected; some will be absorbed, but none will be transmitted.

See also: *Refractive index.*

CRITICISM OF PHOTOGRAPHS. Frequently photographs are submitted for appreciation, criticism and discussion at club gatherings, in postal portfolios and to the editors of amateur magazines.

Inevitably the opinions thus evoked may reveal more about the person voicing them than about the work they are supposed to evaluate. In fact, art criticism at its best is a literary form in its own right designed to inform or entertain the public or just show off the brilliance of the critic rather than to help the artist to do his job better next time.

Critics. Yet amateurs seeking criticism do so mostly in the hope of benefiting from the encouragement and advice they may receive. Anxious to be helpful, the expert is easily tempted to put forward emphatic views by making the most of any little point he happens to notice or by groping for concrete recommendations, too often based only on his own vague beliefs or established habits of thought.

Firm adherents of some school of thought, ideologists and reformers are notoriously aggravating as critics and so are, of course, active artists who have developed their own individual approach to the very type of work they are supposed to review. The critic with vigorous or rigid standards cannot be expected to possess the necessary tolerance and sympathy for work not on his own level.

And apart from the critic's own qualifications, isolated opinions based on a single piece of work are apt to be misleading. It is impossible to judge another man's work from a single print. The critic must see at least a few of his photographs to be able to detect what the photographer is after, what may be intentional, and what is accidental in his style and technique.

Scope. Certain points merit examination in any photograph.

(1) The photographer's purpose in taking it.

(2) Has his technique been wholly and successfully subordinated to that purpose?

(3) Would it be possible to produce from the negative a better print?

(4) Was the photographer's approach original or imitative?

The purpose of the photographer in making a particular picture must receive first consideration; whether his work appears to fulfil that purpose or fall short of it is, in fact, the only point that really matters. If the man behind the camera happens to be solely concerned with some rare or subtle expression in his subject's face then he should be criticized only on account of anything that may distract from that expression, no matter whether the distracting element by itself represents good or bad photography. Thus not even the degree of technical perfection is an unfailingly reliable guide to criticism.

Yet technical criticism proper is compara-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

tively easy or, at least, harmless, even if it leads into errors. Objections like "This is over-exposed, this is unsharp, this is too contrasty" can be readily checked and so possibly refuted by anybody looking at the same picture. Often enough what may appear to be a technical fault is a deliberate mark of style.

Critical suggestions about how to trim a print, angle it differently, throw back this detail or bring out that, may serve a useful purpose, as long as all this advice does not conjure up an altogether new conception unrelated to the photographer's real intention. Criticism is reasonably safe if it is confined to discussing shifts of emphasis rather than to changes in subject matter; it may usefully suggest leaving out something from the author's work but it would be grotesque for it to demand the inclusion of anything additional. You can criticize only what is there.

Limitations. The critic ventures on to very shaky grounds indeed once he airs ideas of his own about how the picture should have been taken. He can seldom be sufficiently acquainted with all the relevant conditions to be able to pronounce really valid opinions on them. What is still more important, he is never in the position to prove his point if challenged. Judges in court aim at judgements which are both just and appear to be just; by the same token, critics must aim at opinions which are both justified and can be proved to be so.

This condition is not met by setting forth the critic's ideas in diagrammatic reconstructions which purport to represent some pictorial analysis or outline an improved version of the photograph criticized. Diagrams are very useful to picture some general statement, but in order to translate a particular photograph truthfully they would have to be drawn, not by hand, but by the same lens that took the picture and at the same spot where it was taken. Sketches not only eliminate most photographic values but may distort and evade awkward issues by using a non-photographic idiom. It is just as futile to suggest improvements to a photograph in an elegant drawing as it would be to try to correct a piece of sculpture by whistling a tune about it.

The critic is privileged to appear clever at the expense of the work criticized but it is an abuse of that privilege to make up arguments extraneous to the subject, to pronounce opinions as if they were rules and to claim ultimate authority in a realm of abstract speculation where none can possibly exist. Any honest critic realizes that as it is his job to be an expert in afterthought, he should at least try to avoid any pretence to creative talents. "Creative" criticism is a contradiction in terms. A critic should offer the product of his experience, knowledge and skill acquired from studying the work of others rather than his own creative urges, prejudices and frustrations. Looking at a print he may be able to suggest that the photographer ought to take more care of his technique or that he should change some of his tools or that he might just as well give up the game altogether. But, being another man with eyes and ideas of his own, he can never take a hand in the actual work without turning it into something that was probably never intended.

A.K.-K.

CROMER, G. 1873–1934. French photographer. Owner of a famous collection on the history of photography, the greater part of which is now at George Eastman House, Rochester, N.Y.

CROOKES, SIR WILLIAM, 1832–1919. British physicist. Investigated the spectral sensitivity of the wet collodion process into the ultra-violet. With John Spiller devised the first "dry" collodion process, 1854. Used light filters for the photography of coloured objects (1854–60). Founder in 1858, and for five years editor of the *Photographic News*. He was Secretary of the Royal Photographic Society in 1857.

CROPPING. American term for trimming of a print. In its wider sense it applies not only to physical cutting, but also to the elimination of unwanted picture areas in printing—i.e., trimming to improve composition.

CROS, CHARLES, 1842–88. French doctor, poet, philologist and painter. Discovered in 1881 the imbibition process, and was a notable pioneer in the theory and practice of three-colour photography (1869).

CROSS, CHARLES FREDERICK, 1855–1935. English industrial chemist. Patented in 1890, with E. J. Bevan, the Primuline process—the first successful method of diazo printing.

CROSS FRONT. Term indicating that the lens panel of a camera may be moved laterally to bring the lens to the right or left of the central optical axis.

See also: *Camera movements.*

CRYSTAL. A crystal is a piece of a homogeneous substance with a spontaneously formed regular geometrical structure characteristic of that substance. The structure may be a simple one or a derivative of a simple shape—e.g., developed from a cube, prism or pyramid. When, for instance, a saturated solution of a substance in water is further concentrated by evaporation, some of the dissolved substance may deposit in the form of crystals.

If crystals of some compounds are heated, they give off a certain amount of water (water of crystallization) and change into an anhydrous form. Such crystals are called hydrated.

Many photographic chemicals are obtainable in both hydrated crystalline and anhydrous forms. These obviously differ in the weight of

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

active chemical present, but often they also differ in their chemical characteristics. So it is most important to know which form is intended when making up solutions from formulae.

See also: *Chemicals.*

CRYSTAL VARNISH. Clear varnish used for giving a protective finish to lantern slides and transparencies.

CRYSTOLEUM. Coloured positive made by combining a transparency and a hand-coloured image. The method is no longer popular.

CUBIC CENTIMETRE (C.CM. OR C.C.). Unit of volume in the metric system equal to 16·9 minims. In scientific work the millilitre (ml.) is largely used instead. For photographic purposes the difference between 1 c.cm. and 1 ml. is negligible.

See also: *Weights and measures.*

CURL. A number of sensitized materials—in particular, papers—tend to curl after processing. This is because of the difference between the shrinkage of the emulsion coating and its support.

The first roll films were troublesome in this way until it occurred to the manufacturers to coat both sides of the celluloid with gelatin—only the coating on the front being sensitized. This produces an even drying tension on both sides of the support so there is no tendency to curl. Modern films that employ certain plastic bases are less prone to curl.

There are several ways of flattening papers that curl after processing.

Certain photographic papers have a strong tendency to curl before use. It is best to minimize this either by keeping boxes containing the paper full, or by compressing the paper in some way within the box. Once curled, the paper should be straightened with extreme care, to prevent stress marks, and cracks in the emulsion, the latter being a particular risk with glossy surfaces.

See also: *Drying.*

CURVATURE OF FIELD. One of the off-axis aberrations of lenses, which causes the plane of focus to be curved.

See also: *Aberrations of lenses.*

CUSTOMS. Photographic equipment taken out of the United Kingdom by a photographer for his own use and brought back again by him is admitted duty free if the Customs Officer at the port of landing is satisfied that the articles are of British manufacture and, if not British made, that they had not been previously imported without payment of any duty properly due.

Purchase Tax is normally not payable if the Customs Officer is satisfied that the articles have already borne tax and that they are in substantially the same state on re-importation as when they were taken abroad—e.g., that the lens has not been exchanged for a costlier one.

The equipment must be produced to the officers on re-importation, with any evidence which can be produced in support of its title to free admission—e.g., a bill from a retailer in this country showing when and where the articles were purchased or the original customs receipt.

The Commissioners will not issue certificates to passengers leaving this country for articles contained in their baggage, nor will they keep a record of any such articles pending return.

Photographic equipment brought into the United Kingdom by tourists from abroad is usually admitted without difficulty provided the equipment is for the personal use of the owner. It must not be sold or otherwise disposed of during the owner's stay, unless duty and tax are paid first.

Customs regulations in other countries mostly follow a similar pattern; a reasonable amount of equipment for a tourist's own use is admitted (usually consisting of one still and one cine camera with accessories and 5–6 films). However, residents of the country may have to pay whatever duties and taxes are applicable.

Returning residents of the United States are granted a $100 customs exemption provided they have been outside the United States for at least 48 hours and have not claimed an exemption in the last 31 days. In addition, there are restrictions on foreign equipment bearing certain trade marks owned by firms in the U.S.A. Such trade marks must either be obliterated, or the owner of the apparatus must obtain a release from the American owners of the trade mark. Certain firms have also given a blanket release permitting a specified number of articles of their brand to be brought in without any restriction.

If in any doubt on current regulations, it is wise to contact the local office of the Customs and Excise Department for full details and also, if necessary, the Embassy or Legation of the country to be visited, who could clarify the position as related to their own regulations.

CUT FILM. Form of negative material similar to roll film but in flat sheets made to the standard plate sizes and now generally used instead of glass plates.

See also: *Films.*

CUTTING. Operation of trimming and joining film shots together; in its wider sense also the timing of such shots in length. A single instantaneous transition from one shot to another is a cut.

Cutting can be regarded as the more mechanical side of film editing, and the person who does this in a motion picture studio is the cutter—usually an assistant to the editor. He handles a print of the whole film specially made for edit-

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

ing purposes, this is known as a cutting print. The original or negative is cut to match it when editing is completed, and then carefully stored for making final release prints (but never projected).

See also: *Editing.*

CYAN. Name applied to the blue-green colour reflected by a surface which absorbs red, for which reason it is also referred to as minus red. It is one of the three primary colours used to form the image in subtractive colour processes, the other two being minus blue (yellow) and minus green (magenta).

CYANOTYPE. (Blue print.) Printing process giving a white negative image against a blue ground.

See also: *Blue print; Document copying; Ferroprussiate process; Printing processes (obsolete).*

CYCLE. Complete single unit of a repetitive movement, variation or event, or sequence of such movements or events. The cycle is a convenient way of describing both the sequence and the rate at which it is repeated (in cycles per unit time).

CYCLIC VARIATION. The voltage V plotted against time T rises to a maximum, drops to zero, reverses direction to a negative maximum and returns to zero. This constitutes one cycle (dotted arrow) after which the process repeats itself.

A cyclic variation always implies a change which periodically returns to its starting point. Graphically, the simplest cyclic variation is a sine wave, which can plot the change of voltage, light intensity, sound amplitude, etc. against time.

In referring to light or other radiation, the cyclic frequency is the number of waves that pass a given point per second. This depends both on the wavelength and on the speed of propagation.

Applied to an alternating current of electricity, the cycle is a single complete fluctuation in potential from zero, through the positive maximum, back to zero, the negative maximum and to zero again.

Applied to sound, the cycle is again a complete wave and the frequency in cycles per second is the number of waves passing a given point. The human ear can hear sound vibrations from about 20 to nearly 20,000 cycles per second.

See also: *Frequency, Sine wave.*

CZECHOSLOVAKIA. The discovery of photography met with an immediate response in the Czech lands. The Czechs and Slovaks in no way remained behind the other civilized nations of the world, either in the early daguerreotype or in the wet collodion process or subsequently in other fields of photography. They also made their contribution to the progress of photography.

Contributions to Photography. Among the leading figures was Dr. Josef Petzval, a native of Spiešká Bělá in Slovakia, who as early as 1840 designed a lens of good quality with a high speed—for that period—of f 3·6. Thanks to him it was possible to cut the exposure time of daguerreotypes to several seconds.

The great reformer, philosopher and poet Jan Evangelista Purkyně (born in Libochovice in 1794) perfected a stroboscope for viewing animated pictures through a slotted disc, and in the 1860's, with his instrument known as the cinescope—i.e., motion viewer—for the first time used a series of photographic snapshots to portray motion. In this way he undoubtedly contributed to the speedier development of cinematography.

Photography also captured the attention of Jakub Husnik, 1837–1916, a professor of drawing in Prague, who in 1863, after numerous attempts, produced two-tone photography. By studying the effect of light on dichromates, Husnik made the discovery, in 1869, of a collotype process. He also discovered a process emulsion for the photography of originals yellowed with age.

Karel Václav Klíč, 1841–1926, painter, photographer, journalist, satirist, caricaturist and printer discovered a technique of heliogravure and copper plate printing which makes possible the speedy and perfect copying of half-tone photographic reproductions. In 1879 he perfected the first photogravure process. In 1895, working at Lancaster and Accrington in England with improvised lighting equipment, he etched the first intaglio copper cylinder (rotogravure).

J. Mahler perfected the method of observing stereoscopic pictures by utilizing the phenomenon of polarization in the form of vectographs—i.e., stereoscopic pairs differentially polarized and printed or projected as a single image which is subsequently split up into right and left eye pictures when viewed through suitably oriented polarizing spectacles.

Contemporary colour photography technique, utilizing colour-forming units, is based on Fischer's and Homolka's discoveries of 1912. Benno Homolka, a German chemist of Czech origin, discovered carbo-cyanine dyes for colour sensitizing panchromatic emulsions.

Photographic Education. The historic Karlova universita (Charles University) in Prague encourages the study of scientific photography. This is directed by the Institute for Scientific Photography, Photographic Chemistry and

CC-0. Agamnani Digital Preservation Foundation, Chandigarh

Photographic Physics, which is part of the Physics Department at the Fakulta přírodních věd (Faculty of Natural Science). The student may study these special subjects when he has completed four terms on the basic syllabus. The University primarily encourages research work, but at the same time provides an education suitable for production work in the photographic industry.

The Department of Photography at the Průmyslová škola grafického umění (Industrial School of Graphic Arts) in Prague and the Department of Photography at the Vysoká škola umělcko průmyslová (High School of Industrial Arts) in Brno both provide training suitable for practical photographers.

At the Brno Vysoká škola umělcko průmyslová, photography is taught either as the main subject or as a supplementary subject in other fields—e.g., the graphic arts. The studies include drawing and design (drawing ability is demanded in the entrance examinations) physics, chemistry and various art subjects.

The growing demands placed on photography to-day have necessitated a considerable extension of the education of young photographers. Third year students at the Photographic Department of the Průmyslová škola grafického umění in Prague are therefore divided into special groups such as medical photography, archive and museum photography, display art photography, etc. They are given every opportunity to co-operate with scientific institutes and the press.

The highest educational institution of art and film photography in Czechoslovakia is the Filmová fakulta při Akademi musických umění (Film Faculty at the Academy of Music and Dramatic Arts) in Prague, which has a special department for film cameramen, where the techniques and aesthetics of static and film photography are taught.

Besides these institutions the Ministerstvo Kultury (Ministry of Culture) and the Ústřední ústav lidového umění (Central Institute of Folk Art) sponsor courses in photography and home movies for amateurs. Attending these courses every year are workers from factories and offices who, upon completion of the course, co-operate with the regional bodies of the National committees to develop photography and home movies either as members of advisory committees in regional and district organizations, or as consultants at local advisory centres of folk art or as instructors in photography and movie making to hobby groups attached to factories.

The magazine *Czechoslovak Photography* also deals with the ideological and specialized training of photographers. Its editorial board co-operates with representatives in all fields of Czechoslovak photography. The task of the board is to use the magazine to increase popular interest in photography and to raise the artistic level of photography. A quarterly review *Fotografy*, printed also in Russian, tries to establish firm views on art and the aesthetics of applied photography. It also aims at maintaining a contact between photographers from East and West.

Photographic Organizations. Amateur photographers are members of photographic circles at the factory trade union clubs. To-day there are several tens of thousands of photographers organized in works' clubs, educational centres for adults, youth and young pioneer organizations.

For their benefit, exhibitions, courses and lectures are organized. For example, the Advisory Committee for Photography at the Dům Kultury (House of Culture) in Prague sponsors lectures on such subjects as: photographic theory and composition; colour photography; creative understanding of press photography; aims of photo art; photographing architecture, landscapes, etc.

Besides this, there are smaller groups of photographic workers in Czechoslovakia. These are, in particular, the photographic artists organized in the photographic section of the Svaz československých výtvarných umelcu (Union of Czechoslovak Artists); photoreporters, organized in the Svaz československých novinářů (Union of Czechoslovak Journalists); and professional photographers who, since 1946, have been organized in co-operative and communal enterprises.

Industry. Although the Czechoslovak precision and optical industry is long established, it has made its greatest strides in the past fifteen years. During this period several factories have been merged into a single enterprise which controls production of diverse products at various branch establishments.

The Meopta Works make enlargers, projectors both for amateurs and professionals, telescopes, laboratory instruments, lenses, microscopes, and a wide variety of accessories as well as still and movie cameras. Between 1946 and 1960 production increased by nearly 700 per cent. The goods produced are exported through the Kovo Foreign Trade Corporation to some seventy countries throughout the world. The largest market is in Great Britain, Canada, the U.S.A., West Germany and Eastern Europe.

Artistic Outlook. In artistic photography there is no desire to ape the art of painting. On the contrary it is taught that, if photography is to gain the respect it deserves as the youngest creative art, it must rid itself of the typical influences of painting. This means, first and foremost, that photographers should aim at pure photographic expression and the preservation of the character of photography.

It is life, movement, spontaneity, naturalness and truth that correspond most closely to the character of photography. The essence of photography is documentation and its choice of themes from daily life is unlimited.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

Photography must not seek to remove itself from life in special forms of expression. The most modern photographic technique is an achievement of advanced science and a product of workers' hands; it permits us to capture what no other field of art can. Its mission is to reflect reality. It can fulfil this aim only if it speaks a language which is not only understandable and clear, but possesses a content and form which are rich and beautiful. In this way photography can become a significant factor in raising the creative abilities of ordinary men and women and in developing their taste and artistic understanding.

V.J.

D

DAGRON, PRUDENT RENÉ PATRICÉ, 1819–1900. French photographer. Patented, 1860, microphotographs with Stanhope lenses set as jewellery and in souvenirs; they were produced on collodio-albumen dry plates. During the Siege of Paris 1870–1 Dagron worked for the official pigeon post service, by which photographically reduced messages were carried.

DAGUERRE, LOUIS JACQUES MANDÉ, 1787–1851. French artist, inventor of the diorama (1822) and of the daguerreotype. He and, independently, Niépce worked on the fixation of the image obtained in the camera obscura. The inventors were brought together by the optician Charles Chevalier, in 1826, and signed in 1829 an agreement on co-operation "for the further improvement of the invention of Niépce which was perfected by Daguerre". The decisive step in the invention of the daguerreotype was Daguerre's discovery (1835) of the possibility of developing with mercury vapour the iodized silver plates the partners had been using. The final step was to fix the picture with sodium chloride (1837). The first report of the discovery was made by the French physicist Arago, on 7th January, 1839, to the French Academy of Sciences. The publication of the process followed on 19th August, 1839. A printed handbook was published at the same time. The process was bought by the French Government and given "free to the world" on 19th August, 1839—but had been patented in England, Wales and the Colonies five days earlier. The coming of the daguerreotype aroused vivid interest over the whole of the civilized world, and for some years the process was popular. Its one grave defect, that it produced one original only, was the cause of its gradual replacement by negative-positive processes whereby copies could be produced. Biographies by Mentienne (Paris 1892), G. Potonnié (Paris 1935), H. & A. Gernsheim (London 1956).

See also: *Discovery of photography; Niépce, J. N.*

DAGUERREOTYPE. Photograph taken by the method published by Daguerre in France in 1839. It consists of a positive image formed by mercury vapour on a polished coating of silver on a copper plate.

There are five steps in the daguerreotype process:

(1) Preparing. A sheet of copper carrying a coating of metallic silver (produced by electroplating, or by the Sheffield plate process) is buffed to a very high polish.

(2) Sensitizing. The plate is exposed to iodine vapour in a light-tight "iodizing box" until it is uniformly covered with an orange coating of silver iodide. This coating is light sensitive.

(3) Exposing. The plate is exposed in a camera for anything up to twenty minutes in bright daylight. The camera lens was sometimes equipped with a reversing mirror since the image produced is a reverse (right to left) positive.

(4) Developing. The image is developed by exposing the plate to the vapour of mercury heated to 140° F. (60° C.). The mercury amalgamates with the silver and clings to the highlights.

(5) Fixing. The unused silver iodide is washed off with a weak solution of sodium hyposulphite (common salt solution was used originally).

After washing, the image is now permanent; the highlights consist of a milky deposit of mercury amalgam and the shadows of plain polished silver.

Daguerreotypes went out of fashion after the introduction of the wet collodion process.

See also: *Discovery of photography; Sensitized materials history.*

DALLASTYPE. A modification of Paul Pretsch's photo-engraving process, reintroduced in 1863 by Campbell Duncan Dallas, one-time manager of Pretsch's Photogalvanographic Company.

CC-0. Jangamwadi Math Collection. Digitized by eGangotri Digital Preservation Foundation, Chandigarh

DALLMEYER, JOHN HENRY, 1830–83. Optician and lens manufacturer in London (of German descent), connected by employment and later by marriage to the Ross family. Produced portrait lenses based on Petzval's design; patented (in 1866) the Rectilinear lens which is very similar to Steinheil's aplanat. Made photoheliographs.

DALLMEYER, THOMAS RUDOLPH, 1859–1906. English optician, son of John Henry Dallmeyer. Introduced to England a telephoto lens based on the Porro-Steinheil design, for which he received the Progress Medal of the Royal Photographic Society in 1896. Was President of the R.P.S. from 1900 to 1903.

DANCER, JOHN BENJAMIN, 1812–87. English optician and microscopist in Liverpool, later Manchester. Made the first photomicrograph in England by the daguerreotype process, 1840, and in 1853 was the first to make microphotographs (by the collodion process). In the same year Dancer made the prototype of a binocular camera proposed by Sir David Brewster, which did not go into production until 1856.

DANCING. As a subject for the camera, dancing shares all the problems of photography of fast-moving subjects by poor light and it has certain limitations, some of which are common to theatre photography. Straightforward flash-photography may be employed for factual records but ballet and other dance-forms call for a more sensitive interpretation. The work of the professional dance photographer is mostly confined to ballet, although many of its problems apply equally to other types of dancing.

A series of ballet pictures should convey something of the atmosphere and theme of the ballet. Lighting should be planned to illuminate supporting dancers, as well as the principals, whilst favouring the latter. Good composition and lighting are very important, followed closely by careful choice of the precise moment for exposure to capture (or imply, in a posed shot) the feeling of the movement. This is of special importance in pictures taken close to the dancers. A knowledge of ballet terms, attitudes and working methods, as well as familiarity with the particular ballet being photographed, is almost indispensable. And permission to take photographs is always essential before commencing.

Choice of Negative Size. Prints of dance photographs are commonly 12 × 15 ins. and larger in size. They must be produced very quickly and be of superb quality, even when part of a negative is enlarged to cut out some supporting dancer's faulty position—a recurring nuisance. So it is not surprising that a ballet company will often supplement the pictures taken by a 35 mm. expert with other photographs taken by a specialist using a larger negative size. These pictures are posed at a special photo-call. The equipment and technique are very similar to those employed by photographers who specialize in theatre photography. Usually in fact a specialist theatre photographer is called in, and it is difficult to distinguish between the pictures of an expert in this field and the best of the 35 mm. action pictures.

Pictures from larger negatives are of superior photographic quality and it is easier to produce large numbers of prints from them quickly for display and press distribution. Some specialists use the 2¼ ins. square negative, but the leading British stage photographers tend to prefer quarter-plate or even larger sizes. The twin lens reflex, the larger single-lens reflex and the view camera are all used by different specialists.

There are three recognized ways of taking ballet photographs: by normal stage lighting, with special lighting, with synchro flash.

By Normal Lighting. Stage lighting is much more contrasty than it appears to the eye. If recorded photographically, it is apt to be over-dramatic and not always appropriate to the nature of the production. So as a rule, the general, non-directional, illumination should, if possible, be increased when the stage spots are the main source of light. Under these lighting conditions professional ballet photographers get good results with 35 mm. miniature cameras. Wide aperture lenses and the fastest films are necessary, particularly for taking photographs during a public performance when no additional light can be used. Earlier workers often employed various methods of hypersensitization and even today the fastest emulsions are only just good enough at the speeds demanded by the action. A shutter speed of 1/100 or 1/125 second at *f* 1·5 can be used with a fairly fast type of film. This gives very little latitude when combined with development in a low energy formula to give fine grain, but this shutter speed and aperture are frequently required for the faster movements of a dancer.

BASIC LIGHTING PLAN FOR DANCE SHOTS. Directional lights at each side of the stage provide the main illumination, while a floodlamp close to the camera fills in harsh shadows.

CC-0. Agamnigam Digital Preservation Foundation of Chandigarh

Special Lighting. The depth of field required demands an aperture of $f/8$ or $f/11$ at most and this means correspondingly longer exposures. For this reason certain dance movements must be omitted from a series of posed pictures. Professional stage photographers generally bring their own lighting equipment to the theatre. Two 500-watt high-efficiency spotlights, one or two 1,500-watt floodlamps and several 250-watt hand-lamps make a typical collection. With this lighting and careful choice of the "dead moment" of a climax or change of direction in the dance, exposures of $\frac{1}{4}$ or $\frac{1}{2}$ second may be made. By sensitive handling of these lamps and suitable directions to the dancers before exposure, the expert can recapture the true atmosphere and movement of the dance. With such lighting, and high-speed panchromatic plates or films, there is ample latitude for fine-grain development to a low gamma.

Theatre assignments have to be carried out in the shortest possible time as the cost per hour for rehearsals is high. Only a handful of photographers have achieved success in this sphere.

Synchro-Flash. Reliable and controllable synchro-flash equipment has made it possible to combine the advantages of snapshot technique with the pictorial and practical advantages of the larger camera. While the pressman's flash-on-camera secures only a record devoid of atmosphere, independently mounted flash units coupled remotely to the shutter contacts are capable of much more subtle effects in experienced hands. Some experiment is necessary to be able to predict the precise contribution that the combined flashes will produce; but a photographer with experience can produce in this way photographs possessing much of the atmosphere of the production itself.

The photographer must attend several rehearsals, and take notes of the most suitable moments for the pictures he will take at the photo-call when the company is his to command for an hour or so. The flash lamps are arranged before each scene, and the movements of the dancers are modified, if necessary, to suit his composition. The exposure is then made with the dancers in action, actually performing the particular part of the ballet. With ordinary flash bulbs, the shutter controls the actual exposure by opening for the required interval—e.g., 1/50 to 1/125 second at the peak illumination of the flash bulb. With the electronic flash tube the highest shutter speed—e.g., 1/500 second—may be used, because the duration of the flash is from 1/1000 to 1/5000 second. This is so short that the fastest human motion is too slow to blur the image.

Whether such speed is an advantage in dance photography is a matter of opinion. When there is no suggestion of blur some of the illusion of motion is lost, and many ballet photographers prefer to use photographable bulbs which, besides being compact, reliable and reasonably inexpensive, permit some control of the degree of blurring of the faster-moving parts of the subject. With properly designed circuits (usually series-capacitor-ignition) there is no limit to the number of bulbs which may be synchronized to fire simultaneously. The lampholders, etc., and associated equipment are portable and light in weight; but where large numbers of pictures must be taken, the cost of bulbs becomes prohibitive.

Electronic flash costs little in use, beyond its transportation cost, although this may be considerable because of the bulk and weight per unit of light-output. But the initial cost is high, and at least two linked units of 200 joules output each are needed to cover quite a small ballet group.

In both kinds of flash photography of the ballet the usual flash–distance–aperture factors for the particular materials employed may be used for a start; but the individual worker will have to modify the figures later to suit his own processing technique and the kind of picture he wants to make.

Other Dance Forms. It will seldom be possible actually to pose the dancers in a ballroom, even an exhibition couple at rehearsal. An opportunist technique will be more appropriate, with high-speed film and large-aperture lenses. The shutter-speed and aperture should be set to suit the lighting conditions (which will often be very poor indeed) and zonal focusing adopted, i.e., the focus is pre-set for the distance at which the best opportunities are expected to occur. This decision, and the choice of the most interesting moments in the movement, can be made early in each dance. The exposure is then made when the couple enter that zone for which the focus has been set.

Exhibition dances, by one or two couples only, will offer the best pictures, especially if the dancers are spotlighted.

Folk dancing and national dances are usually performed in the open air, so almost any hand camera may be used. Keeping the traditional nature of such dancing in mind, it is sound to include, as background, such of the surrounding location and audience as is likely to emphasize this, so long as it is subordinate to the main subject. A knowledge of the particular dance forms is valuable, enabling the photographer to anticipate the direction and movements.

Cabarets are frequently dimly lit, and large-aperture lenses with high-speed film are necessary. The characteristic atmosphere may be retained if, in a subsidiary manner, spectators at their tables are included in the picture area. The silhouettes of one or two heads framing the main subject, marginally, can be especially effective. J.V.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

DARK CORNERS. Dark corners on a print may indicate that the camera lens is not illuminating the whole of the plate area. This occurs when the covering power of the lens is not great enough for the plate in use. The lens is then said to vignette. The same effect happens when excessive camera movements are used. The remedy is to use a lens with a wider angle of field or to try stopping down the aperture.

Even if no vignetting occurs, the illumination at the corner of a plate is less than that at the centre, being reduced by a factor equal to the fourth power of the semi-angle of field. Naturally, this effect is accentuated in wide-angle lenses.

Dark corners may also be caused by using a lens hood which has an acceptance angle too narrow for the plate size. This cuts the corners of the negative, leaving them clear so that they print out darker than the rest of the picture. Light corners on an enlargement mean that the illumination of the negative is faulty or that the enlarging lens does not cover the negative fully. In a condenser enlarger it may be that the distance between the lamp and the condenser needs adjusting, that the condenser is the wrong focal length or that the lamphouse reflector is of the wrong shape. In a diffuser enlarger, uneven illumination or insufficient diffusion can also lead to dark corners.

See also: *Covering power; Faults.*

DARKROOM

Any room selected for use as a darkroom should have a volume of not less than 400 cubic feet; for comfortable working it should not be smaller than 8 feet × 6 feet × 8 feet 6 ins. high. It should be sited so that it keeps cool in summer, and it should not be near equipment that emits fumes, X-rays or other active radiations unless properly protected.

STRUCTURE

The design of a darkroom and the choice of building materials should be given adequate consideration.

Floor. The ideal floor should be resistant to photographic chemicals, and to staining, water-tight, durable, non-slipping when wet, resilient for foot comfort and a suitable colour. While it is impossible to obtain all these qualities in one material, a compromise can be achieved by selecting a floor that combines the most essential properties. An ordinary wooden floor is unsatisfactory because it is not water-tight and dirt and chemicals will accumulate in the cracks. Also, normal types of concrete flooring will not withstand the destructive action of photographic chemicals.

The two most serious effects on floor coverings are corrosion and staining caused by contact with photographic chemicals. The degree of staining and corrosion is usually dependent on the chemically reactive properties of the pigment of the covering material and the absorptive qualities of the floor material itself. For example, if a material is impervious to liquids, spilt developer can remain on the surface until oxidized, but the residue may still be wiped off with a damp cloth. If the floor covering material is porous enough to permit absorption of the solution, the residue will be difficult to remove and discoloration will be almost certain to result.

The darkroom flooring must permit frequent wet mopping without damaging any ceiling below. This means that, when composition tiles are used, both the adhesive material and the flooring material itself must be water-tight.

No attempt should be made to lay a waterproof floor over an existing floor unless the latter is in good condition. All boards of wooden floors should be solid and fastened securely in place. If the boards move under traffic, they will break up the waterproofing. Concrete floors must be smooth and should show no signs of disintegration.

In every darkroom there is a chance of occasional spilling of water and processing solutions. This creates a potential hazard of slipping and for this reason highly polished or waxed flooring should not be used.

When constructing any of the waterproof floors discussed here, it is general practice to lay a fabric membrane before the waterproof floor is laid. Since paper membranes crack easily, an open-mesh cotton fabric saturated with pitch or a plastic based material is recommended.

Generally asphalt is considered the best possible choice of flooring material and satisfies most of the requirements mentioned. It may be laid in one piece and coved to form a skirting, thus preventing any chemicals attacking the foundation. Any settlement or movement of the building will not cause the surface to crack. If heavy equipment is to be installed, the flooring beneath the load-bearing points should be reinforced. If necessary, asphalt flooring can be removed completely without causing damage to the foundation or sub-flooring. Asphalt is available in a variety of colours and the surface is slip-proof.

There are also many types of P.V.C.-based and non-slip tiling which give excellent results. These materials are more attractive than asphalt but also more expensive. They are resistant to photographic chemicals and are reasonably slip-proof. The main disadvantage lies in the jointing and therefore, if plastic tiles are to be used, the bonding material must be resistant to photographic chemicals.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Walls. The walls should have a hard, smooth finish of light colour; rough surfaces accumulate dust and are difficult to clean. A wall painted with cream enamel or oil paint is easily cleaned and reflects the light. Dark coloured walls have no place in a darkroom.

Tiles make a wall surface that is easily cleaned and has good reflecting properties. They should be set in acid-proof cement to prevent penetration of solutions. This is very necessary where there is risk of contamination from hypo, because hypo in contact with unprotected brickwork and concrete sets up gradual disintegration that is practically impossible to check.

Ceiling. The ceiling should be finished in matt white enamel or oil paint. It should not be lower than 8 feet 6 ins.

Light Traps. It should always be possible to enter or leave a darkroom without admitting any light. A labyrinth that turns through two right angles makes an efficient light trap. The walls should be painted matt-black to prevent reflected light from entering, and a white line, about 2 ins. wide, should be painted at about eye-level to assist entry and exit. No direct light should be allowed to shine in; if necessary there should be a baffle across the entrance.

To save space, double doors or double curtains may be used or, if space is very limited, a curtain across the door can be made to serve. When the light-lock consists entirely of curtains they should be made to open in the centre and have a generous overlap. They should be of thick limp material, well weighted at the bottom, and with a broad white band of tape stitched down each edge to mark the opening. When a curtain is placed across a door, it should be hung from a rod about two feet above the top of the door to allow easy opening and closing. Sliding doors occupy little space but are difficult to make light-proof.

LIGHT TRAPS. Top left: *Heavily curtained door.* Top right: *Two-door chamber.* Bottom: *Doorless labyrinth, with or without curtains. Inside surfaces should be black.*

Windows. If existing windows have to be obscured to make a darkroom, they should have removable shutters so that the room can be flooded with daylight. This is a great help when the room is given a periodical clean out. Blinds are a practical alternative to solid shutters that fit closely into the window frames. They must be made of completely opaque, tough material and should run in grooves deep enough to prevent light leaking round the edges. There are two other points that must be light trapped: the housing for the roller, and the recess into which the free end of the blind fits when it is drawn.

Ventilation. A good air circulation is most important and is frequently overlooked because people are apt to shut out the air in an effort to keep out the light. At least 400 cubic feet of air should be allowed for every person using the darkroom and every effort should be made to keep it moving. In small darkrooms, this can be done by fitting a pair of light-tight ventilating units, one at the top and the other at the bottom of a wall, shutter or windows.

Another method is to construct the walls of the darkroom to within 6 ins. of ceiling height and to hang from the ceiling two black painted light baffles about 18 ins. deep, inside and outside the darkroom. Similar light-trapped vents at floor level help to promote circulation of air.

But any darkroom that is in continuous use ought to have an extraction fan. A number of fans are especially made for the darkroom. They are light-trapped and practically silent. They should always be fitted as high as possible.

All vent pipes and ventilators should be matt black inside to make them efficient light-traps.

Drainage. It is NOT safe to drain exhausted developing or fixing baths into a copper drainage system. Ordinary lead plumbing is not affected by the solutions used in the normal darkroom but they should be well diluted.

Sinks should have individual connexions to the main drain and each should have its own trap. A detachable strainer, made preferably of stainless steel, should be fitted to the outlet from each sink. Where the drainage pipes bend at a sharp angle or form a junction with another drain there should be a removable cover or plug to simplify the job of clearing any blockage. Plumbing and pipe-work should be accessible so that attention can be given to leaks and stoppages without unnecessary dismantling and removal of fixed equipment.

FITTINGS

The darkroom lighting should be as bright as is consistent with the speed of the sensitive materials being handled. This can be best done by indirect illumination, reflected off the ceilings and walls, from a properly designed safelight fitted with interchangeable screens

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

COMMERCIAL OR INDUSTRIAL DARKROOM. This type of room may be used for the photographic department of an industrial firm or of a hospital. A, film drying cabinet. B, white light. C, trimmer. D, darkroom timer. E, ceiling light for general darkroom illumination. F, darkroom lamp for local illumination of "dry" bench. G, enlarger. H, contact printer (may if necessary be replaced by a second enlarger). I, glazing machine. J, shelf for measures, bottles, etc. K, processing tanks in "wet" bench; replaced by dishes when required. L, immersion heater for tanks or dishes. M, darkroom lamp for local illumination of "wet" bench. N, rotary print washer. O, wall bracket for film hangers.

of suitable colour. Where the ceiling is broken or of poor reflecting power, the safelight should have a white-painted reflector suspended above it. The general illumination should be supplemented by direct lighting where necessary, e.g., over the processing dishes and the sink.

If two sets of safelighting are used—for example, one for negative development and one for printing—the switches for the brighter lights should be built into a wall-box with a flap cover to prevent people from switching them on by accident. The white light switches should always be boxed in separately or fixed about 18 ins. above the normal level for light-switches. Switches controlling direct safelighting are best placed under the edge of the bench near the lamps concerned.

Safelight lamps should either be hooded or hung below eye level so that they cannot shine directly into the eyes of the darkroom workers. The white light should be placed close to the surface of the ceiling and as near the centre of the room as convenient in order to give as few and as short shadows as possible.

It is useful to have a white light over the sink so that prints can be looked at immediately after fixing. A daylight lamp in a deeply hooded shade can conveniently be suspended over the fixing dish or washing tank. If controlled by a foot switch, it can be flicked on for the few seconds necessary to check print quality. In the same way a small illuminated opal, attached to the wall behind the sink, serves for scanning negatives by white light after fixing.

Safelights. When the correct safelight is chosen for the sensitized material in use, it is possible to have ample light to work by. Papers require yellow, yellow-green or orange safelighting according to whether they are chloride, chloro-bromide, or bromide emulsions. Slow, blue-sensitive materials can be handled by orange safelighting; orthochromatic negative materials require deep ruby lighting, but panchromatic materials call for indirect illumination by a special dark blue-green safelight, and even then they must be examined only very briefly.

Temperature Control. The darkroom should be kept at an even temperature somewhere between 65° and 70° F. And since it is easier to heat a room and its contents than to cool them, the darkroom should be in a part of the building where it is more likely to be too cold rather than too hot.

Where there is no steam or hot water central heating, tubular electric heaters or convectors provide a convenient form of heating.

Since the recommended temperature for most photographic processing operations is 68° F. (20° C.), the solutions used should be

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

brought to this temperature and if the temperature is within this range, the rate at which their temperature changes will be very low. This is also the most comfortable working temperature.

Large dishes and tanks containing processing solutions are most conveniently heated by electric immersion heaters, thermostatically controlled to switch off at the right temperature. Tanks in continuous use are best immersed in a thermostatically-controlled water bath. This gives finer control than individual immersion heaters and it is the system generally used in colour photography, which demands a high degree of reproducibility in processing. Dishes can also be satisfactorily warmed or cooled by a water bath. There are many types of thermostatically controlled individual electric dish warming stands, but for handling a number of dishes the water bath method is cheaper and more convenient.

Benches. Darkroom work benches are either wet or dry. Processing and making up of solutions are confined to the wet bench; the dry bench is reserved for enlarging, printing and loading sensitized materials. Both benches should be kept as far apart as possible, and the wet bench should be alongside the sink.

Teak is the traditional wood used for making wet benches, but there are many other materials as good: i.e. stainless steel or plastic sheet. All these materials may be used very effectively as a covering for the top of the wet bench. Wood which is used uncovered must be made waterproof by coating it with wax. Precautions must be taken to prevent solutions spilt on the bench from running down the back at the line where the bench-top joins the wall. If lead is used to cover the bench, it should be continued up the wall 6 ins. or the joint may be sealed with a strip of beading rendered water-tight with a sealing compound, pitch or other waterproof adhesive.

Bench-tops of dry benches should be covered with thick linoleum, rubber or compressed resin-impregnated fibreboard edged with oak. The covering may be continued up the wall to prevent dust from collecting in the corner.

The average operator prefers to stand at a bench 3 feet high and sit at a bench 2 feet 6 ins. high. All working benches that are not open at ground level should have toe recesses about 3 ins. high and the same depth.

Cupboards and Drawers. The space under benches is usually the most suitable place for cupboards and drawers. The cupboard space under the wet bench should be reserved for storing bottles of solutions in frequent use and for small developing tanks. The space under the sink can be divided up into compartments to take developing dishes in various sizes, standing on end. A number of compartments should be provided over the dry bench for safe-light screens. At least one of the drawers should have a light-tight sliding lid inside so that sensitive material can be left in the drawer without risk of fogging. One type of drawer has a safe lid that slides into place as the drawer is closed and remains closed the next time the drawer is pulled out.

The atmosphere in the darkroom is generally damp, so bulk stocks of sensitized materials should always be kept in another place. But one of the cupboards or drawers in the darkroom should be set aside for storing materials in actual use.

Every darkroom needs a waste bin, and it is as well to separate paper and film waste from glass to reduce the danger of accidents.

Sinks. A shallow darkroom sink can be used as a wet bench for most of the processing. It should be about nine inches deep and rather higher than usual to give as much comfort as possible when working. Hot and cold water should be available and the taps should be

PROFESSIONAL PRINTING DARKROOM. This is divided into two sections, one for contact printing, and one for enlarging. Many professional photographers do not make contact prints at all, in which case the contact room becomes unnecessary. A third room serves as finishing room for glazing, mounting, trimming, retouching, etc. The "wet" benches carrying the developing dishes are arranged along the dividing wall together with the sinks for preliminary washing. A, one of several lamps providing local illumination. B, contact printer. C, ceiling lamp for general darkroom illumination. D, processing bench. E, electric hot glazer. F, work table for retouching and mounting. G, enlarger. H, trimmer.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

high enough to allow a standard 2-gallon bucket or a Winchester bottle to stand under them (i.e., at least 15 ins).

The hot and cold taps should have different types of handle, or one of them may have a spot of luminous paint so that they can be easily distinguished in the dark.

An anti-splash device or a piece of rubber hose may be attached to the cold tap for washing out tanks and dishes or swilling down the darkroom floor (if the hot tap is left without a hose, it serves to distinguish it easily from the cold water tap in the dark).

If the water supply is contaminated by solid matter like grit or rust from the mains, a filter may have to be fitted in the water-supply line.

Suitable sinks may be made of wood (teak, cypress or maple) porcelain, chemical stoneware or stainless steel. Wooden sinks should be coated with asphalt, rubber or a sheet plastic, or lined with lead (not less than 5 pound thickness). All the seams of lead-lined sinks should be burned-in and not soldered. Bitumen-lined sinks are very practical and, although they wear in use, they can be repaired without difficulty.

Duckboards on the floor of the sink prevent breakage of dishes and glassware and stop dishes and tanks from slipping about. Draining boards alongside the sink are made of wood, or —where expense is no object—stainless steel. Some sinks have a cover which can be fitted over the top to form a useful extra bench when the sink is not in use. G.B.M.

Electrical Equipment. Most of the darkroom electrical equipment is in use only intermittently and is thus usually connected into some sort of switch-plug. All such plugs should be of the three-pin type with the third pin properly earthed. The frame of all pieces of metal equipment should be connected to the third pin of the plug. This greatly reduces the risk of shock.

It is wise to provide more socket outlets than are, at the time, thought to be necessary. Darkroom equipment is frequently being added to and multi-way adaptors are no more than a dangerous expedient. It should be made a strict rule to connect only one piece of equipment to any socket outlet or point.

The average small darkroom might reasonably have the following electrical equipment:

ELECTRICAL INSTALLATIONS. The various units are as far as possible fed from a number of lighting and power points, and controlled by individual switches. A, darkroom lamp and switch for general illumination. B, outlet point and switch for enlarger or printer. C, electric clock (needs no switch). D, white light and special boxed switch to prevent accidental switching on during working. E, tubular heater fed from power point. F, darkroom lamp and switch for local illumination of work bench. G, extractor fan in blacked-out window. All switches within reach of the sink and wet bench should be of the cord-operated, ceiling fitting type.

ELECTRICAL INSTALLATIONS

Equipment	*Power Consumption—Watts*	*Total Watts*	*Total Current at 230 volts*
White ceiling light ...	60		
Safelight, general ...	40		
Safelight, local	15		
Contact printer ...	100		
Enlarger	100		
Fan	60	375	1·6 amp.
Clock	Neglible		
Dish Heater	100*		
Print Dryer and Glazer	250*		
Kettle	1,500*		
Room Heater	2,000	3,850	16 amp.

* These items would not normally be all switched on at the same time and would be adequately served by two independently fused 15 amp. circuits or as a ring main, by two 13 amp. sockets. One socket outlet would be reserved for the room heater and the other would supply any two of the other units.

These items would be supplied by two sub-circuits, i.e., a 5-amp. lighting circuit and a 15-amp. heating circuit. The various items would then be conveniently installed as follows.

White ceiling light: suspended from ceiling. Controlled by switch near door (a key switch prevents accidental fogging of materials).

Safelight, general: hanging from wall over dry bench. Controlled by switch near dry bench socket outlet.

Safelight, local: hanging from wall between wet bench and sink. Controlled by cord from switch located in the ceiling.

CC-0. Abdul Jalil Digital Presevation Foundation, Chandigarh

Contact printer: fitted with 5-amp. plug to connect to socket outlet on right-hand end of dry bench. Controlled by own switch which is usually built-in.

Enlarger and fan: as for contact printer.

Clock: connected through clock fuse to 5-amp. subcircuit permanent wiring.

Room heater: on floor, with flex to reach 15-amp switch socket outlet to right of dry bench 5-amp. socket outlet, clear of dry bench top, so that heavy flex can fall straight from socket outlet to floor. Controlled by socket switch for on and off, and own switch from 1,000 to 2,000 watts.

Dish heater: with flex and 5-amp. plug to 5-amp. switch socket outlet at left hand end of dry bench. Controlled by socket switch.

Kettle: with flex and 5-amp. plug to connect to same switch socket as dish heater.

Safety Precautions. Commercial darkrooms and processing establishments come under the Factory Acts and any electrical equipment must conform to the regulations set out in the Electricity Supply Regulations, the Electricity Regulations of the Factory Acts and the Wiring Regulations of the Institution of Electrical Engineers.

The electrical wiring and equipment in amateur darkrooms must conform to the Electricity Regulations governing domestic electrical installation. Normally the electrical installation is done by a contractor who knows what the regulations require and it is inspected by a representative of the Electricity Authority before the supply is connected. However most darkroom equipment and wiring is installed and added to by the occupier and may not always be up to the required safety standards. The following safety measures are basic to any installation and are intended as a guide for amateurs without any knowledge of electricity.

Earthing.—All portable darkroom electrical equipment should be connected to a 3-pin socket outlet by a 3-core flexible cable so that all metal cases and exposed metal parts are connected to earth automatically when the equipment is plugged in. The only exceptions are lighting fittings which are out of reach and not in the way of normal darkroom operations. If anything goes astray inside properly earthed equipment and a live part of the circuit comes into contact with the chassis or case, the fuse will blow. Without an earth connexion the case would be made live and anyone touching it would get a shock which could be fatal.

Wet Bench.—No switches or socket outlets should be mounted within reach of the wet bench. It should not be possible for anyone working at the wet bench to operate a mains switch or insert a plug in a socket. Any switching should be done by a cord connected to a ceiling switch as used in bathrooms (and other places where the operator is likely to be in wet contact with water pipes or other main services connected directly to earth). F.P.

IMPROVISED DARKROOMS

For the simpler tasks in photography—e.g., changing plates or freeing a jammed film in the camera—an easy and simple substitute for the use of a darkroom is to crawl into bed head first, making sure that there are no light leaks round the body, and carry out the work in darkness under the clothes at the foot of the bed.

To load film into the developing tank, drape the bedclothes over the arms and shoulders while sitting on the floor with the legs under the bed. But by far the better way is to use the bathroom or the space under the stairs; the essential is that the place be light-tight and clean.

Under Stairs. See that the door when closed is light-tight and there is no extraneous light. Any gaps can be filled up by tacking strips of felt around the edge of the door. Take extra care that any electrical meters or mains are protected from splashes of water or accidental contact.

There must be a shelf, box or table covered with lino where sensitive materials can be handled without fear of water, solutions or dry chemicals coming into contact with them. There must also be a space for the processing dishes or tanks for negatives and prints. Washing can be carried out in the kitchen sink.

For printing in a confined space of this type the best method is to use a printing box which can either be bought ready made or contrived from a wooden box with a little ingenuity and thought. The printing box and safelight can be electrically operated from the mains or from a battery.

The walls can be painted up to 42 ins. with an acid-resisting black paint and above this and on the ceiling with a light colour such as cream or yellow. The floor should be rendered waterproof if possible with a covering of lino or, if it a cement floor, with traffic paint.

Shelves should be fitted wherever possible in odd corners to take bottles, etc.

It is not essential to have photographic dishes, for use can be made of suitable kitchen dishes and pails for washing water and waste.

Bathroom. An ordinary bathroom can be converted into a darkroom in this way: make the window light-tight by means of a well-fitting black blind running in grooves or behind slats. Then arrange a working surface over the bath.

A tray for processing with 2 ins. lip all round, made of plastic or plywood, can fit the top of the bath for half its length, while the other half is covered by a plywood bench to take the printing box or enlarger.

To prevent the light of the contact printer or enlarger from fogging the paper whilst being developed and also to prevent splashes of solution on sensitive material, a partition about 9 ins. high can be placed between the tray and the bench.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

CONVERTED BATHROOM. To be practical, the conversion must be simple and quick, with little preparation before, or clearing up after, use. In this case a wooden rack fits over the bath and takes the dishes and other gear connected with processing. The enlarger stands on a suitable table or low cupboard which may house all other accessories when not in use. The only lengthy part of the conversion may be the task of blacking out awkwardly placed or shaped windows.

Illumination can be by a safelight or by fitting one of the special coloured bulbs in the ceiling light. As in all darkrooms, great care must be taken when fitting any temporary electrical switches and equipment to ensure that there is no possibility of an electric shock. A small distribution board providing fused socket outlets for the various pieces of equipment can be connected to the nearest 15-amp point by a length of three-core cable. All wire should be of a waterproof covered type and all circuits properly earth-connected.

With a little thought the tray and bench can be constructed so that when not in use they form a box to store the dishes. If there is space available in the bathroom, a small cupboard should be fixed to store solutions, chemicals and measures, etc.

Spare Room. Where there is a spare room available for conversion specially for photographic work, the layout will naturally depend on space available and the nature of work to be undertaken.

The room should be so arranged that at least one bench can be kept dry for the sensitive material while it is in the dry state. All wet operations should be carried out on a second bench (the wet bench) with a sink next to it. It must be impossible for splashes of working solutions to reach the dry bench. Similarly the benches must be made so that hypo, etc., cannot drip on to the bench or floor.

Where possible the wet and dry benches should be on opposite walls or at right angles. An ideal working bench would be 33 ins. high and up to 18 ins. wide.

The space under the dry bench can be divided in two, one half as a cupboard for storage of cameras, lenses and sensitive material. Chemicals, whether in bottles or dry packages, should never be stored in this cupboard. The other half of the space can be divided up to take a drawer at the top and a shelf with space underneath for mixing pail and stirring rods, etc.

The Darkroom Trolley. In small flats where space is at a premium, the darkroom trolley offers a way of fairly rapidly converting a normal room into a darkroom for printing and enlarging. The trolley consists of a sideboard-size cupboard on wheels and containing an enlarger, developing dishes and solutions, and storage for other incidental equipment (timer, etc.) and paper. When not in use, everything is contained inside the cupboard which can be wheeled out of the way against one wall of the room. When required for darkroom work, the top of the trolley becomes a working surface and carries the enlarger, a space for dry manipulation, and the processing dishes. A swing-up flap may increase the working area.

Setting up only requires blacking out the room. Darkroom illumination may be provided by a coloured safelight bulb, placed in, for instance, a reading lamp in place of the normal bulb. The working surfaces are preferably coated with plastic; if this has a wood pattern finish, the whole unit can look like a normal piece of furniture when not in use.

It can also have space for film developing tanks and film processing equipment; the room only needs blacking out for sufficient time to load the film into the tank, after which processing can take place in ordinary lighting without any further preparation.

Darkroom trolleys are usually designed individually, frequently by amateurs with some carpentry skill. They have on occasion been offered commercially.

A compact enlarging darkroom along similar lines is the wardrobe which contains the enlarger on a shelf, plus a folding table for the processing dishes and storage for all other equipment. A darkroom safelight may be built into the wardrobe. To get it ready for work only involves setting up the table, opening the wardrobe doors and blacking out the room. When not required all equipment is unobtrusively shut away inside.

CC-0. Kashmir Digital Presevation Foundation, Chandigarh

SPECIALIZED DARKROOMS

Darkrooms for various specialized work are as numerous as the variety of work, but they still have the basic principles of a tidy, dust-free and well-ventilated, dry room and a layout suitable to the photographic task involved.

Photo-Finish Darkroom. One example is the type used in connexion with photo finish cameras, where the photograph (an 8 × 10 ins. enlargement) of the result of the race must be in the hands of the judge in the shortest possible time. This is built in a stand or a tower about thirty feet above the ground.

An average size for such darkrooms is 6 × 8 feet; the camera is off-set to one end of the 8 foot side of the darkroom.

All pieces of equipment are installed as near as possible to each other but still leaving plenty of working space.

SMALL PHOTO-FINISHING LABORATORY. The darkroom contains three working places round a central bench carrying individual developer and stop bath dishes and a common fixing tank. Here two workers use contact printers or roll-head printers, the third on an enlarger. The daylight room contains the final washing, glazing, and other finishing equipment. A, contact printer or fixed-ratio roll-head printer, B, central processing bench. C, washing-tank. D, light-trapped hatch. E, trimming bench, F, sorting and dispatching bench. G, enlarger. H, special enlarger, I, light-trapped doors. J, mounting bench.

Taking the camera as the starting point of the processing operation and working clockwise, the order in which the equipment is laid out is: camera, film processing unit (with thermostat to control solution temperatures), fitted flush to the bench, safelight flush with the bench to enable the negative to be placed correctly in the negative carrier of the enlarger, fixed enlarger and paper carrier, print processing dishes, sink and dry bench.

To attain high speed of production, all the work must be carried out with the negative wet. It is therefore vitally important for the whole electrical circuit to be efficiently earthed. All switches and plugs are positioned at the most convenient place for the operator to reach without unnecessary movement. Every piece of electrical equipment is separately fused on a fuse board in the darkroom and all fuses plainly marked to enable a quick replacement to be made. The floor and benches are covered with lino with a good acid-resisting, hard-wearing surface. The walls are painted acid-resisting black up to 42 ins. and cream above.

Ventilation is effected by louvre type ventilators under the benches and an extractor fan on the wall. Heating is carried out by tubular heaters under the benches.

X-Ray Darkroom. In general, this follows the same lines of organization as any professional darkroom. In certain cases, however, it must have provision for rapid processing, e.g., when a radiograph is required during a surgical operation. This mainly involves careful temperature control and a suitable working layout of benches and equipment so as to waste as little time as possible.

Most darkrooms of this type have a light-trapped service hatch where the exposed films are handed in, and the processed radiographs passed out. Where rapid processing is used, the finished radiographs are examined wet in front of a suitable viewing box.

MOBILE DARKROOMS

Although not as necessary now as in the days of wet plates, there is still a limited requirement for portable and mobile darkroom equipment in the field.

Portable Darkrooms. Changing bags are made of a light-weight and lightproof material, in the form of a bag large enough to take camera, dark slides and plate boxes, and fitted with two sleeves with elastic openings for the arms. The whole can be folded into a very small size and packed away in the camera case.

For use on a job at a remote place there is an igloo type of tent in which a limited amount of work—e.g., developing negatives and making contact prints—can be carried out. No poles are required. This type of tent is packed in a box that when unpacked becomes the work table. The tent is made of a light-tight material;

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

along the four edges which come to a point at the top are sewn rubber tubes that can be inflated to form structural members, thus giving a rigid conical-shaped tent. The door is fitted with a zip fastener and the walls of the tent have flaps which tuck under the tarpaulin forming the floor, thus making all light-tight. The main use for this type of tent is to enable an operator on a long task away from the main studio—e.g., when shooting a film or taking part in an expedition—to check his results.

Full-sized darkroom tents are mainly used by the Armed Forces in the forward area and consist of a double-lined tent of about 20 × 20 feet, the inner lining being of a black light-tight material.

The interior of the tent is divided into three rooms: one room, taking half the space, forms the work room for drying, trimming, sorting, mosaic making; a second room, taking one-quarter of the space, is for negative processing and the third room is for printing and enlarging.

The door is usually zip fastened and the tent walls and floor covering overlap to prevent light leaks. All the tentage and equipment are packed in suitable cases designed so that when unpacked they become useful articles of darkroom furniture such as tables, chairs, sink, etc. The equipment includes a small, petrol-driven generator with a distribution board and waterproof leads which connect with suitable points in the tent for safelights, etc. An extractor fan is inserted in a hole in the tent wall and a small pump lifts water from a tarpaulin tank to the sink.

Lorries and Trailers. A mobile darkroom is built on a lorry and fitted out to deal with processing of plates or films, quick drying and contact printing. The principal use is for on-the-spot processing of news and sport pictures in remote districts for transmission by wire or radio.

The Royal Air Force use a darkroom trailer of this kind (T Type) in the field. These trailers are equipped to deal with aerial photographs from the 4 × 5 ins. type camera and have side awnings fitted for use as a workroom. They provide their own electric light from a small generator and may be fitted with a refrigeration plant for use in tropical climates.

Photographic Train. The extreme example of a mobile darkroom is the Royal Air Force train of four articulated vehicles more than thirteen feet high and over thirty-two feet long and weighing more than twelve tons. They are used with forward area units responsible for photographic reconnaissance. Such a train consists of the following vehicles.

(1) An office for administration, keeping records of work carried out, sorting and dispatch of prints, numbering and examination of negatives.

(2) Film processing unit capable of automatically processing and spooling up to 500 exposures of 9 × 9 ins. format film at a speed of about four feet per minute.

AIR FORCE PHOTOGRAPHIC TRAILER. All the equipment for processing and printing the aerial films is housed in a trailer 15 feet long and 7½ feet wide. A, film processing room, separated by curtain. B, printing box. C, spool with negatives. D, ventilation fan. E, print trimmer. F, controls for refrigeration unit under dry bench. G, water supply tank. H, sink with processing dishes. I, darkroom lamp (several are arranged around the trailer). More advanced trailers contain automatic film processing units for dealing with continuous lengths of up to 500 exposures of 9 × 9 ins. film at a time.

(3) Printing section fitted with a multiprinter which automatically produces and finishes prints from the 9 × 9 ins. film at about 1,000 prints an hour.

(4) Darkroom for manual processing of films in a series of tanks and drying on a large drum.

(5) Darkroom for manual printing and finishing.

(6) Trailer with a heavy duty generator that supplies the electric current required to operate all the equipment.

To complete the train there are several trucks (3 ton and 15 hundredweight) for film storage, stores, tentage, and all the paraphernalia necessary to make a completely self-contained unit. S.J.H.

DARK SLIDE. Name sometimes used for a sheet film or plate holder. If the holder carries two sheets the term "double dark slide" is used.

DAVANNE, ALPHONSE, 1824–1912. French amateur photographer. Contributed to half-tone photolithography and wrote numerous books and articles on photography. Was one of the founders of the Société Française de Photographie (French Photographic Society) and consecutively Vice-President, President and Honorary President of its Council (1866–1912).

DAVISON, GEORGE, 1856–1930. English civil servant and amateur photographer. Follower of P. H. Emerson's Naturalistic Photography; founded the Impressionistic school of photography in 1890. Founder member of the Linked Ring, 1892. Managing Director of Kodak Ltd., 1898–1912.

DAVY, SIR HUMPHRY, 1778–1829. English chemist. Experimented in collaboration with Thomas Wedgwood before 1802 in the production of silhouettes and contact copies of leaves, etc., on white paper or leather moistened with silver nitrate and chloride solution, and under the microscope, but could not fix them. Discovered the electric arc light in 1813. Biography by J. C. Gregory (1930).

DAY, WILL, 1874(?)–1936. English cinematographer and pioneer of the cinema. Part of his large collection on the history of cinematography (and of its forerunners) is now in the Science Museum, London.

DAYLIGHT

The sun is the source of all daylight. Even when it hides behind a cloud, it provides the light that we see—and take photographs by. Direct sunshine at noon in the middle of summer has an intensity of 10,000 foot candles —equal to 400 Photoflood lamps placed 6 feet away from the subject, and almost a thousand times stronger than the artificial light illumination in an ordinary living-room.

But the strength of the sunlight is not constant; it varies throughout the year from one month to the next and throughout the day from one hour to the next.

It varies because the sun's altitude changes throughout the year and from the beginning to the end of the day. The sun is highest in the sky, and therefore its light is strongest, in June, and it is lowest, and its light is weakest, in December. In the course of the day the strength of the light varies in the same way from sunrise to noon, and from noon to sunset.

Both the yearly and daily patterns are regular—March and September lie at equal distances from the June peak and so have the same strength of sunlight; the sunlight is as strong at nine o'clock in the morning as at three o'clock in the afternoon.

The visible spectrum of uninterrupted sunlight extends from 4,000 Angstrom Units (violet) to over 7,200 Angstrom Units (red). All the coloured rays it includes in its range add up to make white light.

But sunlight is a commodity which the photographer rarely, if ever, has to deal with in its pure state. Photographs are made, not by sunlight, but by daylight, and the two are not by any means the same thing. In daylight some light always comes from the sky, and some often comes from reflections off nearby surfaces.

The direct rays of the sun are white, they travel in straight lines, and all the straight lines come directly from the sun. But daylight is more often coloured than white (generally more bluish than direct sunlight); to a large extent it is able to find its way around corners, and it comes from all directions, even from below.

Daylight is a variable mixture; part consists of white light that has arrived straight from the sun, and part of light that has been changed in direction or colour, or both.

The Direction of Daylight. The direction of the light that shines on the subject may be affected by the surroundings. Certain objects—white clouds, light painted buildings, snow, chalk cliffs and masses of sand or water, can act as reflectors. Under the right conditions they can even provide the principal lighting. When sunlight is reflected by such surfaces, it scatters in all directions and no longer casts hard shadows.

A similar scattering takes place when the sunlight has to pass through atmospheric moisture in the form of thin cloud, mist or raindrops. Denser forms of atmospheric moisture—heavy cloud and fog—completely destroy any appearance of direction in the light, and cast no shadows.

The Strength of Daylight. The strength or intensity of the daylight is governed by the altitude of the sun and the weather.

The altitude of the sun varies according to the latitude, the time of year, and the time of day. In practice, however, these factors do not affect the strength of the daylight as much as might be expected: the sun at midday in June is only about half as strong again as in January for similar weather conditions. Finally, careful research has shown that daylight quickly increases in strength once the sun is clear of the horizon. From then, thanks to the fact that it is helped by sky and cloud reflection, it remains at about the same strength for the greater part of the day. Towards evening the strength falls

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

off again as quickly as it increased in the morning.

The weather, in fact, has a much greater effect on the strength of the daylight than any other factor. Cloud or fog can make a June afternoon as dark as December, and a sudden change in the weather at any time can raise or lower the light intensity by ten times in the space of a few minutes.

Exposures in Daylight. The correct exposure in daylight photography depends as much on the quality of the daylight as on its strength. But while the strength or intensity can be measured by an exposure meter, it is not as easy to judge the quality. The quality of daylight is a combination of contrast and colour. Both can affect the exposure profoundly.

Contrast. Lighting contrast depends upon the amount of direct sunlight present in the daylight. The strongest contrasts are seen when the sun shines out of a clear sky and there are no clouds or reflecting surfaces to illuminate the shadow areas of the subject. When photographs must be taken under such conditions, it is common practice to give a very full exposure and curtail the development time of the negative (in other words, expose for the shadows, and develop for the highlights).

This procedure flattens out the contrast of the negative and can be made to yield an acceptable picture instead of a useless example of "soot and whitewash". In strong, clear sunshine it is safe to double the normal exposure and reduce development of the negative by a third to a half.

CONTRAST OF DAYLIGHT. Top: *Direct sunlight yields high contrast with brilliant highlights and deep, sharp, shadows.* Centre: *Veiled sun gives softer light with clearly visible, but considerably more luminous shadows.* Bottom: *An overcast sky gives a lower level of even diffused illumination with virtually no discernible shadows at all.*

INTENSITY OF DAYLIGHT. The squares represent the relative amount of light given by the sun from a clear sky at different hours of the day and in the various months of the year for a latitude of 45–55° N. The circles show the relative altitudes of the sun at noon, and also the proportion of hours of light. In Great Britain this table applies for Greenwich Mean Time. During the months of Summer Time, one hour should be added to all the times shown.

At the other end of the scale there is the type of daylight where there are no direct rays from the sun, and the shadow areas are so illuminated with reflected light that they cease to count as shadow areas. This sort of lighting can occur when the sun is completely obscured by heavy clouds or fog and equally when it is veiled in white mist. Both of these conditions give lighting of low contrast, although one is very much more intense than the other.

In low-contrast lighting the exposure must be kept to a low value and, if possible, development should be extended. This increases the contrast of the negative and prevents the print from looking flat and lifeless.

At the same time, there is a danger of losing contrast by giving too short an exposure. If the exposure is just sufficient to record detail in the darkest shadow and there is not much difference between that and the strongest highlight, it is quite possible for the whole exposure scale to lie on the toe of the characteristic curve. When this happens, the negative will develop to a low contrast because the slope of the toe of the curve is less than that of the straight line portion.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

So ideally, in this kind of daylight, the exposure should be just enough to register the deepest shadow (in which detail is to be shown) on the bottom of the straight line portion of the characteristic curve.

Between the contrasty lighting of the direct rays of the sun and the flat, diffused illumination found in mist, fog or rain, there are infinite possibilities of variation. Fortunately modern sensitive materials possess very wide latitude which looks after quite large errors in exposure. And the number of grades of printing paper is enough to look after quite large errors in judging contrast. So that it is only necessary to override the normal exposure meter reading for the more extreme contrast variations in daylight.

The Colour of Daylight. The atmosphere always contains a certain amount of water vapour. Finely divided droplets of water in this form act as a colour filter, letting yellow, orange, red, and infra-red rays through and reflecting blue, violet and ultra-violet rays. So, an observer looking at the sun through mist or fog, sees it as an orange-red disc, while if he stands with his back to the sun, the mist itself appears blue-white. Motor-car headlights seen through fog appear dull orange, but to the driver behind them they appear as a dazzling white.

So the water vapour in the air tends to colour the daylight orange and to rob it of blue rays. And the more vapour the light has to shine through, the more orange the daylight appears. Morning and evening light are both inclined to be redder than broad daylight; when the sun is low down on the horizon its rays travel obliquely through the vapour layer and so pass through more of it.

When daylight is reflected it takes up the colour of the reflector. As reflectors are usually white or almost white (clouds, snow, painted buildings, etc.) this is rarely important to the black-and-white photographer. But coloured reflecting surfaces must be handled with care in colour photography where the blue sky or reflected light from a grassy bank, or the red brick wall of a house outside the picture area may upset the colour values of the subject.

For black-and-white exposures, the photographer needs to trouble about only the extreme conditions. These are usually encountered early and late in the day, when the sun shines through relatively large amounts of water vapour. As water vapour holds back blue and violet light the daylight at such times is redder than usual. In terms of practical photography this means longer exposures, particularly with orthochromatic films and plates, because they are not very strongly sensitive to light at the red end of the spectrum.

Daylight at High Altitudes. There is generally less water vapour and dust in the atmosphere at high altitudes than at lower levels. One result of this is that the light falling on the scene is not scattered as much as usual and distant detail is clearer. There is also less air above the scene, which means less scattered light from the sky. So the landscape, which is normally seen by the camera as being much darker than the sky, appears almost as bright.

DIRECTION OF THE SUN. The direction of the light determines the relative areas of light and shade in the subject. Front lighting illuminates the whole visible area of the subject; as the sun moves round, the camera sees progressively more of the shaded side, until everything is in shadow.

At low altitudes the excess of blue light from the sky must be held back by a filter or the sky will come out as a blank white area on the print. But at high altitudes the balance of brightness changes and the sky tones will generally be reproduced satisfactorily without a filter. If anything more than a very pale yellow filter is used at high altitudes, the sky tones are apt to be unnaturally dark.

The absence of light-scattering water vapour also means that the light at high altitudes is rich in ultra-violet rays. The camera lens is not corrected for these rays, which thus tend to upset definition. Under such conditions, the scene can be reproduced with greater clearness by using a U.V. (ultra-violet) filter. This special filter is practically colourless, and while it allows ordinary visible light to pass through unimpeded, it is opaque to ultra-violet light.

Character. What has been said above about photography by daylight is concerned only with making an acceptable negative—i.e., one that is correctly exposed. But all the variable factors in daylight have their effect on the aesthetic character of the photograph.

The direction of the lighting has a special

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

significance in daylight photography, because it can indicate the time of day when the photograph was taken. So the mood of the scene is very largely suggested by how the light falls. Low slanting sunshine with long shadows generally suggests evening for the very good reason that most people are more familiar with the long shadows of late evening than with the long shadows of early morning. The general mood of such a photograph is one of rest, quiet, and meditation. So the angle of the sunlight adds a significance of its own in addition to the effects of direction common to all other forms of lighting.

The colour of the daylight affects the tone values of the photograph in the same way as a filter. It makes no difference to the final result whether the light is filtered before it falls on the subject or before it enters the lens; coloured light is simply light that has been filtered before it falls on the subject.

So, early and late in the day, and in misty seasons when the light is yellowish, the tone values of the scene are changed as they would be by a yellow filter—i.e., green, yellow, orange and red objects become lighter in tone and other colours, including the blue sky, are relatively darker. At such times there is nothing to be gained by using a filter, as the light has been filtered already.

The diffusion of the light by fog, mist, clouds, and irregular reflecting surfaces, can make all the difference between a soft, well-modelled picture with a multitude of grey tones, and a hard, strongly etched study with only two or three tones between black and clear white. Generally, when the light is well scattered, it tends to destroy surface texture, although that can be an advantage in playing down wrinkles in portraiture. Such lighting gives restful effects.

Strong unbroken sunshine is suitable for dramatic treatment with a harder effect.

Here also, the character of the daylight almost always has a special significance because it indicates certain weather conditions, seasons, and even actual places—viz., the Alps, the tropics, the English Lakes, are all associated with types of daylight quality.

Supplementing Daylight. When the daylight alone is either not powerful enough or too harsh for photography, other light sources may be brought in to help. Flash, both bulb and electronic, or electric lamps may be used as a modelling light, under dull conditions, to simulate sunshine while the daylight provides the fill-in lighting. Or the artificial lighting may be used from the camera position to brighten up the deep shadows cast on a subject by direct sunlight. Such illumination can serve the further purpose of brightening a subject taken against the light.

With black-and-white material any of these light sources may be used quite safely. With colour material the colour temperature of the light has to be taken into account. The colour temperature of daylight may be anything from 4,800 K° (English daylight) to 7,500 K° (American daylight) while the colour temperature of artificial light may be anything from 2,600 K° (ordinary tungsten lamps) to 4,000 K° (flash bulbs). This means that ordinary tungsten and even photoflood lamps cannot be used. (The colour of such lighting would reproduce with an unpleasantly yellow-orange cast.) Special blue flash bulbs with a colour temperature of 6,000 K° and electronic flash (colour temperature 4,800°–6,000 K°) can be combined with daylight without any disturbing distortion of the colour values. F.P.

DAYLIGHT ENLARGER. Early type of enlarger which employed diffused daylight as a system of illumination. The image was projected into a darkened box or room.

DAYLIGHT PRINTING. Simple way of making a positive contact print from a negative, using daylight to make the exposure. At one time was a widely employed amateur procedure with printing-out papers (P.O.P.).

See also: *Contact printing; Papers.*

DEBABOV, DIMITRI GEORGIEVICH, 1901–49. Russian press photographer and artist. Originally an actor, he eventually became permanent photo-correspondent to *Izvestia*. Specialized in photographs documenting Arctic life. Died from a venomous insect bite while photographing hunters in the Taiga.

DECKLE EDGE. Name for the decorative wavy or ragged edge given to some photographs. A deckle edge may be obtained with a special print trimmer.

DEFINITION. Term in photography indicating the fineness of the detail in a negative or positive print. The standard of definition is affected by the ability of the lens and the photographic emulsion to resolve distinct lines (the resolving power) and the scale of contrast of the emulsion. A line is only clear when it is both sharply resolved and is distinctly darker or lighter than the adjacent tones.

See also: *Acutance; Circle of confusion; Grain; Lens testing; Negative materials; Resolving power.*

DELAMOTTE, PHILIP HENRY, 1820–89. English water colour artist and photographer. Professor of drawing at King's College, and

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

organizer of the photographic department of the Manchester Art Treasures Exhibition in 1857. In 1855 published 160 photographs of the rebuilding of the Crystal Palace at Sydenham.

DELAYED ACTION. Automatic operation of the shutter at some time after the shutter release has been pressed. Many shutters incorporate a delay mechanism and there are proprietary devices which can either be attached to the normal shutter control or screwed into the flexible release socket. The delay is generally about 10–15 seconds and gives the photographer time to take up his place in the picture.

See also: *Self-portrait; Shutter release.*

DELIQUESCENCE. Property of a number of substances of absorbing so much moisture from the atmosphere that they finally dissolve in it. Many such substances—e.g., phosphorous pentoxide—are used as drying agents for desiccating the air in storage containers.

See also: *Chemicals.*

DEMACHY, ROBERT, 18??–1938. Paris banker and pictorial photographer. In 1895 he brought the gum bichromate printing process to a high degree of perfection, and introduced modern oil transfer processes for prints in 1911. From these processes the modern bromoil process was developed. Biography by F. C. Lambert (London 1904).

DEMENY, GEORGES, 1850–1917. French scientist and pioneer of moving pictures. Worked from 1882 to 1894 with Marey. Constructed Marey's second Chronographe camera (1890) which used a flexible film in magazines. Designed the Phonoscope (1891–2) for the optical synthesis of motion depicted in a series of photographs arranged round a glass disc. Made in 1893 a chronophotograph with film movement by an eccentric beater; later (1896) developed it into a projector. The apparatus was designed for, and marketed by, Gaumont. Demeny used first 60 mm., later 35 mm. film.

DENMARK. There is no record of the first photographs taken in Denmark, but interest in photography has been strong since the earliest times and today there is a small but active industry in addition to well patronized professional and amateur movements.

Industry. In Denmark there is a factory for films and photographic paper. Some small-scale photographic manufacturing is carried on as side lines by other industrial undertakings. A good deal of this work originates from the second world war, when Denmark was cut off from supplies of tripods, dishes, filters, darkroom accessories and the like from abroad. There are also several types of enlargers made, but these are mainly expensive instruments for professional use. The limited market compels the makers to go in for precision instruments of high quality and high prices rather than cheap mass production. There is an ingenious studio camera in which six or twelve plates are stored in the top of the body. A light touch of a lever makes a plate fall into position ready for exposure and another touch of the lever makes it drop to the bottom of the camera, where the back of the holder covers it and keeps it light-tight.

Professional Photography. The professional photographers are organized in about twelve local circuits, the central administration of which lies with Dansk Fotografisk Forening (League of Danish Photographers), founded in 1880. It was the first Danish photographic society and, although its membership is now exclusively professional, it originally included amateurs.

Professional photographers are trained as apprentices to other photographers for three or four years; in addition they have to take a two-months' course at the photographic school owned by the Dansk Fotografisk Forening. But in Denmark entry to the photographic trade is unrestricted and can be followed by anyone, so a good number of Danish professionals were originally amateurs who—often gradually—turned professional.

Camera Clubs. The first amateur photographic society in Denmark was probably the Københavns Fotografiske Amatørklub (Copenhagen Amateur Photographic Society) which was founded in 1895. It still has an active membership.

There are about 170 camera clubs (practically all of them admitting amateurs and professionals without distinction, but not always photographic dealers). Eighty of the clubs are affiliated to the central organization, Danske Kamera Pictorialister (Danish Camera Pictorialists), which is a member of the F.I.A.P. The D.K.P. provides clubs with programmes for their meetings: portfolios from inland and abroad, lectures in manuscript to be read at the meetings (with accompanying slides), lantern slide series, many of them with typed criticisms, and so on.

The title D.K.P. (Danish Camera Pictorialist) is awarded by the club to photographers (without distinction between amateurs and professionals) who have for a number of years shown distinguished skill and steady interest in pictorial photography, either as photographers or as critics and writers. There are at present forty holders of the title.

Exhibitions. There is an annual national exhibition of Danish pictures which is shown in turn in a number of towns. A set of slides from the best pictures in this exhibition is sent to the neighbouring countries, Sweden, Norway and Finland, with which close collaboration is maintained and which exchange corresponding sets from their own national exhibitions.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

While in earlier days the subjects favoured by Danish pictorial photographers were mainly landscapes and portraiture to be rendered as true to nature as possible, the trend is now towards more sophisticated subjects. Abstract compositions play an increasing part in the exhibitions and a recent analysis showed that less than 3 per cent of exhibited pictures were landscapes (even in the widest sense of the term), and portraits were hardly more numerous. There are no awards whatever and many leading workers refuse to send pictures to exhibitions where awards are given. It is felt that such medals, prizes and the like tend to lower the dignity of photography.

Publications. The only photographic journal of general interest and circulation is *Foto-Magasinet*. It is published by an independent publisher, but as one of the two editors happens to be the president of the D.K.P. there is some connexion with the photographic societies.

There is also the monthly *Dansk fotografisk Tidsskrift*—somewhat smaller, but with a few illustrations. It is the official publication for professional photographers and is only available to members of their organization. *Smalfilmbladet* is the journal of the amateur cine societies. *Foto-Tidende* is the organ of the photographic dealers' society. Some small publications are issued more or less regularly by photographic firms and distributed free of charge for publicity purposes. H.B.J.C.

DENSITOMETRY. Technique of density measurement of silver deposits in any part of a developed photographic image. Can be carried out by transmitted light (e.g., on a negative or transparency) or by reflected light (e.g., on a paper print). The instrument used for such measurement is a densitometer; the results may be used for plotting the characteristic curve of the material concerned, or for exposure determination.

See also: *Colour sensitivity; Density; Sensitometry.*

DENSITY. Exposure followed by processing produces blackening which can be quantitatively measured as "density". A density is measured in a densitometer, an instrument in which the intensity of a beam of light can be measured before and after passing through any selected test patch on the developed image. If I_1 is the intensity of the light before it passes through, and I_2 the intensity after it passes through the test patch, the density D is defined as

$$D = \log I_1/I_2.$$

The ratio I_1/I_2 is often called the opacity, but the inverse ratio I_2/I_1 is more frequently used and called the transparency. Since I_2 is always smaller than I_1, the values for transparencies run from 0–1. If multiplied by 100, transparency values are obtained as percentages.

The density value obtained for any one density patch will depend to some extent on the design of the measuring instrument.

DENSITY. If a beam of intensity I_0 passes through an absorbing medium and is reduced to I_1, the opacity is I_0/I_1 and the density is log I_0/I_1. For a value of I_1 = 1,000, a range of 1,000 to 1 for I_1 corresponds to densities from 0 to 3·0.

When density values are plotted against the logarithm of the exposures which produced them, a characteristic curve of the sensitized material is obtained.

TRANSPARENCY (OR REFLECTIVITY) AND DENSITY

I_1/I_2	Transparency or Reflectivity	Density
1	100%	0
1·25	80%	0·1
1·6	62%	0·2
2	50%	0·3
2·5	40%	0·4
3·3	31%	0·5
5·6	18%	0·75
10	10%	1·0
20	5%	1·3
40	2·5%	1·6
100	1·0%	2·0
1000	0·1%	3·0
10000	0·01%	4·0

Specular Densities. The density of a test patch on a photographic negative can be measured in two ways. The first is important in projection and projection printing. It is known as the specular density and is arrived at by measuring the intensity of the transmitted pencil of light at a distance from the test patch. This method ignores the light that passes through the patch and is scattered sideways at the surface.

Diffuse Density. The second kind of density is

TYPES OF DENSITY. If a medium both absorbs and scatters light, the density measurement depends on the lay-out of the measuring apparatus. A: At d-d all the transmitted light is measured; the density value obtained is the diffuse density, B: At s-s a large part of the scattered light will miss the measuring surface; the density obtained is the specular density.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

important in contact printing. It is known as the diffuse density and is based on a measurement of the total amount of light passing through the test patch. As the diffuse density takes into account all the light transmitted by the test patch, and the specular density measures only a part, the specular density is always greater than the diffuse density. The diffuse density is more easily measured and standardized than the specular density. Thus the British Standard Specification 1384–1947 defines the contact printing density, but makes no attempt to define the specular density. Contact-printing density is obtained by measuring the density patch in contact with a piece of translucent light-scattering material, such as pot opal glass, which is part of the densitometer.

Reflection Density. Reflection density is a measure of the depth of a tone on a surface viewed by reflected light—i.e., a photographic print. It is strictly analogous to the transmission density of an image viewed by transmitted light—i.e., a negative or positive transparency. In reflection densitometers, the measuring light as a rule falls on to the test strip at an angle of 45° and the amount of reflected light is measured at 90°, i.e., at right angles to the paper surface. The light value I_1 is that reflected from the base of the paper, and I_2 is that measured with the density patch in position. The ratio of I_2/I_1 is called the reflectivity.

Reflection density measurements may depend on the physical nature of the surface as well as the density of the image—e.g., the figure for a paper with a pronounced or regular surface texture will vary according to the direction of the incident light. W.F.B.

See also: *Callier effect; Sensitometry.*

DENTAL PHOTOGRAPHY. The camera is used in dentistry to take photographs of the teeth to show dental disease, malformations, the soft tissues, the formation of the oral cavity and frontal and side views of the face. It is here that dental photography adjoins photography in plastic surgery. Its value in orthodontics and maxillofacial surgery is undisputed. Most of these are excellent subjects for comparative photographs where the same region is photographed with visible light, infra-red and ultra-violet to include features not normally visible.

Photography is also used in dentistry in order to demonstrate the physical improvement following treatment. This often imparts a marked—and sometimes dramatic—psychological benefit. Furthermore, a photograph taken in comparative youth will often serve as a model in later life when new dentures are needed to counteract the effects of reabsorption and other changes.

Dental research organizations have carried out mass oral photography of the full upper and lower dental arches of selected groups of the community.

Education of the patient in dental hygiene by photographs is profitable if the subject matter is selected with care; the keynote being to confine the demonstrations to those things that have a direct bearing on the patient's own condition or health.

Equipment. The apparatus employed is simple and compact and it is usually kept available for instant use, generally at the chair-side. A small view camera is often used because it is versatile, permitting scaled photographs up to full size, and it gives accurate visual focusing, selective composition, and allows for the quick interchange of sensitized materials. A roll film, or even a miniature camera needs a special long focal length lens, a supplementary lens, or an extension tube, to get a sufficiently large image at the requisite working distance. Simple equipment may be devised whereby the camera is provided with a series of finder frames and corresponding supplementary lenses. This arrangement allows of very rapid working even by unskilled personnel.

More expensive equipment includes the precision miniature camera, either of the single-lens reflex type or fitted with a reflex housing. In either event, a long-focus lens and extension tubes will be found an advantage. A specialized outfit made for this type of work consists of a miniature camera with bellows focusing and carrying its own lighting close to the lens. The whole unit is mounted on an X-ray tube stand.

Dental mirrors of various shapes and sizes, together with a set of unobtrusive lip retractors complete the equipment of the dental photographer. By such means it is possible to record a full view of the occlusal and lingual aspects of the teeth.

Lighting. Axial illumination—i.e., illumination along the optical axis of the camera—is ideal for a deep cavity such as the mouth. In practice the camera and its light or lights, with or without the distance frame, are mounted together as a composite unit, an arrangement which gives nearly axial illumination. The complete assembly can be mounted on a bracket for instant use. Being close to the subject the light source need only be a small unit—such as a tubular projection lamp—in a non-reflecting

DENTAL LIGHTING. The light is concentrated on the required area of the mouth by means of a concave mirror set up just outside the field of view of the camera lens.

shield. These small sources give sharper detail and fewer troublesome reflections than larger lamps. A small flash bulb or electronic flash tube in a blackened reflector is often employed, and in some arrangements the light is focused on the subject by a concave mirror.

A circular electronic flash tube mounted round the camera lens will be found extremely useful for deep intra-oral views.

Colour. The teeth and associated structures are being increasingly reproduced in colour instead of black-and-white. For colour photographs, more powerful light sources are employed and they are balanced with appropriate filters to suit the sensitized material.

Intra-oral views have a natural background, but when facial views are taken, extraneous objects beyond the subject are excluded by setting up a conventional background—usually green.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Polished metal retractors are apt to give undesirable reflections, and painted finger nails can be even more objectionable. The general light from a large adjacent window—common in a dental surgery—will very often cancel out the advantages of the concentrated illumination of a small light source, in addition to upsetting the colour balance when using colour film.

Technique. Practically every dental photograph is only of real value when compared with another, either of the same, or a different patient. For this reason it is highly necessary to establish a standard technique by which anyone can take regular photographs for comparison without possessing any greater technical skill than that of the average amateur. T.A.L.

DEPTH OF FIELD

When the camera lens is focused to give a sharp image of a particular object, other objects closer or farther away do not appear equally sharp. The decline of sharpness is gradual and there is a zone extending in front of and behind the focused distance where the blur is too small to be noticeable and can be accepted as sharp. This zone is known as the depth of field of the lens. It is often miscalled the depth of focus.

The extent of the depth of field depends, amongst other things, on how great a degree of blur we are still prepared to accept as sharp, i.e. upon the size of the circle of confusion. The stricter the standard of sharpness, the smaller the permissible circle of confusion and the smaller the depth of field.

The depth of field also depends on the aperture and focal length of the lens, and on the distance from the lens to the subject. The smaller the aperture and the shorter the focal length of the lens, the greater the depth of field. The closer the subject, the smaller the depth of field. The limits of the depth of field of a lens are given by the equations:

$$D_n = \frac{D}{1 + Dcf/F^2}$$

$$D_f = \frac{D}{1 - Dcf/F^2}$$

where: D_n = Near limit of depth of field
D_f = Far limit of depth of field
D = Focused distance
c = Limiting circle of confusion
f = *f*-number of lens aperture
F = Focal length of lens

(All measurements must be in the same units.)

For a circle of confusion equal to 1/1000 of the focal length of the lens we have:

$$D_n = \frac{D}{1 + Df/1000F}$$

$$D_f = \frac{D}{1 - Df/1000F}$$

where: D_n = Near limit of depth of field
D_f = Far limit of depth of field
D = Focused distance
f = *f*-number of lens aperture
F = Focal length of lens

Effect of Aperture and Focal Length. With a pinhole camera the depth of field is theoretically unlimited. Everything is reproduced equally sharp, however near or far away, and irrespective of the distance between the pinhole and the film or plate. So the nearer the relative aperture of a lens approaches a pinhole the greater the depth of field at any object distance.

In fact both relative aperture and focal length govern depth of field. The depth of field depends on the ratio of *f*-number/focal length. The larger this ratio, the greater the depth of field.

For an absolute circle of confusion (i.e. independent of the focal length of the lens), the depth of field is proportional to the ratio of *f*-number/(focal length)^2.

Hyperfocal Distance. The depth of field depends also on the distance of the subject: the farther from the lens, the greater the depth of field.

For any one lens aperture, focal length, and circle of confusion, there is a point beyond which the depth of field behind the subject is infinite. The nearest point at which this happens is called the hyperfocal distance. It is also the near limit of the depth of field when the lens is set at infinity.

When a lens is focused at its hyperfocal distance, the depth of field extends from infinity to half the hyperfocal distance. At half

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

DEPTH OF FIELD IN PRACTICE. The extent of the depth of field depends on the focusing distance, the aperture, and the focal length of the lens. First three columns: *The depth obtained increases as the subject moves away from the camera.* Fourth and fifth columns: *With the lens focused on a given distance, the depth of field grows as the lens is stopped down.* Last three columns: *With a given distance and aperture, the use of lenses of increasing focal length again reduces the extent of the sharp zone available.*

the hyperfocal distance, the depth of field extends from the hyperfocal distance to one-third of the hyperfocal distance. At one-third of the hyperfocal distance, the depth of field extends from half to one-quarter, and at one-tenth of the hyperfocal distance the depth extends from one-ninth to one-eleventh.

The nearer the focused distance is to the hyperfocal distance, the greater the depth of field.

The hyperfocal distance depends on the same factors as the depth of field—standard of sharpness (circle of confusion), aperture and focal length of the lens:

$$H = 1000F/f$$

where: H = Hyperfocal distance
F = Focal length of lens
f = *f*-number of aperture

for a circle of confusion = 1/1000 of the focal length.

For a higher standard, e.g. 1/2000 of the focal length,

$$H = 2000F/f$$

For an absolute circle of confusion,

$$H = F^2/cf$$

where: H = Hyperfocal distance
F = Focal length of lens
c = Circle of confusion
f = *f*-number of aperture

All units of measurement must of course be the same throughout.

Simplified Depth of Field. For the same hyperfocal distance (fixed by the focal length and aperture of the lens) the depth of field values are always the same, and depend only on the distance at which the lens is focused. This simplifies depth of field calculations and tables. There is no need to work out the depth of field separately for every aperture and for every lens; it can be related directly to the hyperfocal distance.

In terms of the hyperfocal distance the near and far limits of the depth of field can be found as follows:

$$D_n = \frac{HD}{H + D}$$

$$D_f = \frac{HD}{H - D}$$

where: D_n = Near limit of depth of field
D_f = Far limit of depth of field
H = Hyperfocal distance
D = Focused distance

Used in conjunction with hyperfocal distance tables one depth of field table serves for all lenses and apertures. Once the hyperfocal distance corresponding to the focal length and aperture of the lens is known the depths of field at any focused distance can be read off from the tables.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Example: a 3 ins. lens at $f/12{\cdot}5$ has a hyperfocal distance of 20 feet. Similarly, a $1\frac{1}{2}$ ins. lens at $f/6{\cdot}3$ has the same hyperfocal distance. If we focus either lens at 12 feet, the depth of field will extend from $7\frac{1}{2}$ to 30 feet. Focused at 8 feet, the depth of field will go from 5 feet 9 ins. to $13\frac{1}{2}$ feet, and so on.

Any intermediate values not shown in the tables can be interpolated by simple proportion.

Depth with Interchangeable Lenses. For interchangeable lenses of different focal lengths for the same camera (i.e., the same picture format) the fundamental rules (the first two equations quoted) still apply, but the simplified forms—based on a circle of confusion of 1/1000 of the focal length—do not.

Where the picture format remains the same irrespective of the focal length (which is the case with an interchangeable-lens camera) the circle of confusion must also remain constant. The hyperfocal distance thus depends again on the square of the focal length of the lens. That is why the depth of field for a long focus lens of a 35 mm. camera is much narrower than with a lens of the same focal length used as the normal lens of a larger camera.

Once the hyperfocal distance is known at the different apertures for the normal camera lens, the same hyperfocal distances for the other interchangeable lenses can be determined simply by multiplying the hyperfocal distance for the normal lens by the square of the focal length ratios. For example if the hyperfocal distance for a standard 50 mm. lens at $f\,5{\cdot}6$ is 30 feet, the corresponding hyperfocal distance for a 35 mm. wide-angle lens will be $30 \times (35/50)^2$ = approximately 15 feet. Conversely, the hyperfocal distance for a 135 mm. long focus lens would be $30 \times (135/50)^2$ = approximately 220 feet. The same applies of course to the values for other apertures. The actual limits of the depth of field can again be obtained from the equation involving hyperfocal distance.

Zone Focusing. In action photography it is useful to know what focusing and aperture settings will give sharp focus over the whole range of movement of the subject towards or away from the photographer. Once the camera is set to these figures, no further adjustment is necessary while the subject is in the zone.

All the information for such fixed zone focusing adjustments is given in the ordinary depth of field tables, but for convenience many manufacturers print the figures for a few adjacent zones on a plate on the camera, or engrave the setting on the lens mount.

On some cameras, coloured indicating spots or arrows mark fixed focus and aperture settings which divide the whole range of the camera into no more than two or three zones. Focusing with such cameras is merely a matter of setting the lens to the appropriate Near, Average, or Distant Zone.

Close-up Depth of Field. Close-up pictures call for special consideration.

In copying, for instance, the subject (i.e., the original to be copied) is two-dimensional and there is no question of getting near and far objects sharp. The problem is to find the permissible error in setting up the camera and the subject, which is a matter of depth of focus.

In most close-ups the depth of field is so small that the zone of sharpness is in effect a flat plane, and the correct viewing distance depends only on the scale of reproduction on the final print. The smaller the negative the more it must be enlarged to give a standard scale of reproduction of, say, 1 : 1, so the circle of confusion must be correspondingly smaller.

For close-up work of this kind a suitable limiting diameter for the circle of confusion is about 0·025 mm. on full frame 35 mm. negatives, 0·0005 in. (0·012 mm.) on half frame 35 mm. negatives (as used in microcopying), 0·002 in. on $2\frac{1}{2} \times 3\frac{1}{2}$ ins. (6×9 cm.) negatives, and so on. This is about equivalent to a standard of 1/2000 of the focal length under normal conditions.

While the normal depth of field equations still hold, a value based on the scale of reproduction is often called for.

Also, at such close distances the depth of field is practically the same behind as in front of the subject. The depth of field in front of and behind the plane of sharp focus is:—

$$d = fc(M + 1)/M^2$$

FOCUSING ZONES. Choice of proper lens apertures and focusing distances can yield a series of overlapping zones of depth of field, stretching from infinity to close limits. This obviates individual focusing on the subject, e.g., when there is no time. Top: *Far zone stretching to infinity.* Centre: *Medium zone of average distances.* Bottom: *Near zone.*

Circle of confusion 0·025 mm. The above is the depth of field at each side of the plane of sharp focus. The total depth is twice these figures.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

where: d = depth of field behind or in front
M = Scale of reproduction (image size/object size)
f = *f*-number of aperture
c = diameter of circle of confusion
(all of these measurements in the same units).

This equation holds for close-up focusing with double-extension cameras or with extension tubes.

With positive supplementary lenses there is a change in relative aperture which must be allowed for by multiplying the *f*-number by a correction factor:

$$f_c = f \times S/(F + S)$$

where: f_c = *f*-number of combination
f = *f*-number of camera lens
S = Focal length of supplementary lens
F = Focal length of camera lens

To find the depth of field at close-up distances, ascertain the scale of reproduction for the focal length of the lens used and the focusing distance.

Then find the depth of field for that scale of reproduction and the aperture used in the close-up depth of field tables below.

Correct for supplementary lens if necessary.

Example: With a subject distance of 10 ins. and a 5 ins. lens the scale of reproduction is 1 : 1. If the lens is stopped down to *f* 8, the depth of field as shown in the table below will be 0·016 in. in each direction, or 0·032 in. in all (approximately 1/32 in.).

A 1 : 1 scale of reproduction will also result from using a 10 ins. supplementary lens with a 10 ins. camera lens. If the camera lens is stopped down to *f* 8, the correction factor for the *f*-number (for an object at infinity) is 10/(10 + 10), i.e., ½, and the effective *f*-number becomes *f* 4. The depth of field is then 0·008 in. in each direction, or 0·016 in. altogether (approximately 1/64 in.).

Limits of Sharpness. The depth of field calculations assume that the degree of sharpness corresponding to the chosen limiting circle of confusion is obtainable. There are, however, two reasons why this is not always possible.

(1) At large apertures the definition given by the lens may fall short of the assumed standard. That is because of aberrations which are usually most prominent at large apertures.

LIMIT OF SHARPNESS. Top: *When a lens is properly focused on an object, the rays of light meet in a point on the film or plate.* Centre: *If the object is nearer the lens, the rays meet farther away, and the plate records a blurred disc.* Bottom: *With the object farther away, the rays diverge again before they reach the plate, and also form a blur. This blur, or circle of confusion, is noticeable as a blur only if it exceeds a certain size. Below that size there is thus a range of distances nearer and farther away than the correct focusing distance, which still yield an acceptably sharp image. That range is the depth of field and can be controlled by judicious choice of apertures.*

(2) At very small apertures, the sharpness of the image is destroyed by the diffraction of light at the edges of the diaphragm. The smaller the aperture, the greater the diffraction. The actual depth of field therefore increases much more rapidly than the geometrical formula suggests, again with a limited and progressively inferior image sharpness.

So to keep within any adopted standard of sharpness, the lens must not be stopped down below a certain limiting aperture, depending on the circle of confusion chosen as the standard. L.A.M.

See also: *Aperture; Circle of confusion; Depth of focus; Optical calculations; Zone focusing.*
Books: *Photographic Optics*, by A. Cox (London); *Focal Focusing Chart*, by A. Cox (London).

DEPTH OF FOCUS

When the camera lens is focused on an object there is one position where the image is sharpest. The sharpness falls off as the film or plate is moved away from this position of exact focus. But there is a certain range of focusing movement within which it is not possible for the eye to detect the difference between a sharp and a very slightly blurred image. This zone of latitude is the depth of focus.

The depth of focus depends on the diameter of the circle of confusion, on the lens aperture, and on the distance between the lens and the image.

The depth of focus extends as far in front of the image plane as behind it.

It is given by the formula:

$$d = \frac{cvf}{F}$$

This is the depth of focus at each side of the plane of sharpest focus. The total depth is twice as great. Circle of confusion: 0·025 mm.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

where: d = Depth of focus in either direction
c = Limiting circle of confusion
v = Distance between lens and image
f = *f*-number of lens aperture
F = Focal length of the lens

The total depth of focus, i.e. the total permissible film movement, is twice this value.

In terms of subject distance:

$$d = \frac{cDf}{D - F}$$

where: d = depth of focus in either direction
c = Limiting circle of confusion
D = Distance of subject
f = *f*-number of lens aperture
F = Focal length

The depth of focus is directly proportional to the *f*-number; the larger the aperture, the smaller the depth of focus.

Effect of Subject Distance and Focal Length. As the subject is brought nearer to the camera, the ratio D/(D—F) increases, and the depth of focus also increases. This is exactly opposite to the effect on the depth of field.

And as the focal length of the lens increases, the ratio of D/(D—F) also increases, and with it the depth of focus. This again is the opposite of the effect on the depth of field.

But the effect of the focal length is only appreciable at near focusing distances. If the subject distance is very much greater than the focal length, the ratio D/(D—F) becomes nearly equal to 1. In that case the depth of focus becomes the product only of the circle of confusion and aperture, and is not affected by the focal length of the lens.

DEPTH OF FOCUS AND APERTURE. Depth of focus increases the more the lens is stopped down because this decreases the angle of the cone of rays from the lens. At a small stop, therefore, the diameter of the cone reaches the limiting diameter of the circle of confusion more gradually and the film can be displaced more from the plane of maximum sharpness.

DEPTH OF FOCUS VARIATIONS. Unlike depth of field, depth of focus increases for close subject distances because the cone of rays coming from the lens is longer and more pointed.

Standard of Sharpness. Finally, the stricter the standard of sharpness, i.e. the smaller the circle of confusion, the smaller the depth of focus.

If the diameter of the circle of confusion is 1/1000 of the focal length, the depth of focus is:

$$d = \frac{FDf}{1000\,(D - F)}$$

where: d = Depth of focus in either direction
F = Focal length of lens
D = Distance of focused subject
f = *f*-number of lens aperture

The circle of confusion is not a fixed quantity; it depends on the viewing distance of the final print, on the focal length of the lens, and on the scale of enlargement.

Hyperfocal Distance and Depth of Focus. The depth of focus is related to the hyperfocal distance by the formula:

$$d = \frac{F^2D}{H(D - F)}$$

where: d = Depth of focus in either direction
F = Focal length of the lens
D = Distance of focused subject
H = Hyperfocal distance of lens

The depth of focus given by any one of a range of lenses can be read off directly from the tabulated values of the formula in the tables.

All measurements must of course be in the same units.

To find the depth of focus of any lens set at infinity: look up the hyperfocal distance in the tables, then read off the corresponding depth of focus in the tables.

The tables are accurate within 10 per cent, provided the subject distance is more than 10 times the focal length. Thus for a 4 ins. lens we can use the figures down to a focusing distance of about 3½ feet; for a 5 cm. lens down to about 0·5 m.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Close-up Depth of Focus. At close distances the depth of focus greatly increases. This is clear from the normal depth of focus equation.

In close-up work it is often necessary to know the depth of focus at various scales of reproduction. This is given by the equation:

$$d = c(M + 1)f$$

where: d = Depth of focus in either direction
c = Circle of confusion
M = Scale of reproduction (= image size/object size)
f = *f*-number of lens aperture

This holds only for focusing by camera extension. It does not apply to the use of positive supplementary lenses when the effective *f*-number, and therefore the depth of focus, is decreased. But the same equation can be made to serve by multiplying the *f*-number by a correction factor:

$$f_s = f \times \frac{S}{F + S}$$

where: f_s = *f*-number of combination
f = *f*-number of camera lens
F = Focal length of camera lens
S = Focal length of supplementary lens

A range of values of the formula is tabulated above. The depth of focus of any normal lens used for close focusing can be read off from this table: first find the scale of reproduction for the particular lens and focusing distance, then read off the depth of focus for that scale of reproduction and the aperture used in the tables. (Correct if necessary for change in *f*-number by supplementary lenses.) L.A.M.

DERMATITIS. Name given to a group of skin conditions. Sometimes produced by direct contact with certain processing chemicals.

See also: *Skin affections.*

DERMATOLOGICAL PHOTOGRAPHY. Photography used in the study of the normal and diseased skin. A considerable part of dermatological diagnosis depends upon the visual impression and therefore a useful photograph must portray a condition as observed by the clinician. The main points to be demonstrated are:

(*a*) Distribution—the location and spread of a disease.
(*b*) Shape of a lesion—discoid, circinate or plaque-like lesions.
(*c*) Configuration of edge—well defined, ill-defined or raised.
(*d*) Contour.
(*e*) Texture.
(*f*) Colour.

Penetration of the Skin by Visible and Invisible Radiations. The human skin is a translucent organ consisting of two main layers, the epidermis or surface layer and the dermis. Radiations in the ultra-violet, visible and infra-red bands penetrate the skin to varying degrees. The ultra-violet rays penetrate the surface only, visible light to the epidermo-dermal junction and infra-red into the dermis to the depth of the larger blood vessels. By using either an emulsion sensitive to a particular wavelength band or a light source emitting only one waveband, the photographer may select the "depth" at which the photograph is to be taken.

The definition of the skin surface will be affected by rays reflecting from the deeper layers, and the ultra-violet or blue wavebands are best used when the surface structure is to be portrayed. For the majority of lesions, orthochromatic emulsions produce adequate definition of surface and at the same time improve the contrast between pale red lesions, which predominate in skin disease, and the normal skin. When lesions are medium red in colour a normally balanced panchromatic emulsion is used. If dark red ulcerated lesions are present, a panchromatic emulsion with increased red sensitivity is preferable.

In selecting colour film for colour photography of the skin, preference should be given to an emulsion which has a good colour interpretation of red, as this is the predominant colour in diseased skin.

Lighting. Control of lighting conditions is essential both with tungsten lamps and flash. In the latter case it is preferable to fit a low voltage tungsten lamp to the reflector for modelling control. A directional light source such as a spotlight or small flash lamp in a reflector helps to show up the texture and contour of lesions. Heavy shadows ensuing from this beam should be filled in with a flood lamp or flash lamp with a large reflector. Back lighting can be useful to outline the edge of limbs which might otherwise merge into the background. Lighting ratios should not be greater than 3 : 1 when exposing colour film, but can be increased for black-and-white.

Backgrounds. A plain, unobstructed background is essential and dark backgrounds, such as black or grey, are preferable. For colour photography green or black backgrounds are recommended, the former can add colour contrast to pale erythematous lesions. It is important to keep backgrounds standard.

Special Techniques. Infra-red will demonstrate deep lying vascular structures or underside of scab-like lesions.

Electronic flash exposures with a U.V. transmitting filter over the lens (i.e. absorbing visible light) will emphasize pigmentary differences or changes in the keratin surface.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

U.V. fluorescence photography. Show fluorescence of organisms in the skin and hair which are diagnostic of some fungus diseases. In this case the source should be a U.V. lamp by itself and the lens fitted with a U.V. absorbing filter, so that the photograph only records the fluorescence.

Photomacrography of the living skin requires a special camera set-up with focal frames which fire an electronic flash on contact with the skin. Negative magnifications of up to × 5 can be obtained in this way. R.J.L.

Book: *Longmore's Medical Photography* (London).

DESENSITIZING. Certain dyes, called desensitizers, reduce the sensitivity of an exposed film or plate to light, without greatly affecting the latent image, So they can be used for developing negative materials by a much brighter safelight than usual. This is a great help in development by inspection and factorial development, though in some cases the actual factor is changed by the desensitizer action.

When they have been desensitized, slow orthochromatic materials can be developed by subdued white light, fast ortho films and plates by the sort of orange safelight normally used for bromide papers and fast panchromatic materials by a bright green safelight.

Red safelights are not suitable for desensitized panchromatic material because when certain desensitizers such as phenosafranine are present the red light attacks the latent image.

Colour of the dye has little direct influence on the degree of desensitization. The exact mechanism of the effect is not yet understood, but all the desensitizers may be considered as weak oxidants having the ability to trap photoelectrons that are released within the silver halide grains by the action of actinic light.

Desensitizers are best employed as a forebath. A few can even be added to the developer itself, but many have an adverse effect on the action of the developer. Fine grain developers of the ortho- or para-phenylene diamine type are not suitable for developing desensitized films or plates. Fortunately, these developers are mostly used for developing miniature films in tanks where there is no need for desensitization.

Method. In practice the film or plate is immersed in the desensitizer for 2–3 minutes in darkness, or by the normal safelight. It is then rinsed, transferred to the developer and developed by the appropriate bright safelight. Where the desensitizer is mixed with the developer, the bright safelight can be switched on after about 2–3 minutes development in total darkness.

Dyes. The useful desensitizing dyes are pinacryptol green, pinacryptol yellow, pinacryptol white, and phenosafranin. The first two should only be used as a forebath; the others may be used either as a forebath or in the developer. Phenosafranin has the disadvantage of staining the emulsion red.

A number of proprietary desensitizers are also on the market under various trade names.

An average working concentration is about 1 part in 5000 of water (or developer), usually obtained by diluting a 0·5 per cent stock solution.

Other Desensitizers. The oxidation products of certain developers have a desensitizing influence. For instance, a 1 per cent solution of metol (containing about 0·2 per cent each of sodium carbonate and potassium bromide), which has been oxidized by blowing air through the solution, or by long exposure to the air in an open dish, can be used as a desensitizing forebath. L.A.M.

DETECTIVE CAMERA. Term introduced in 1881 for a small camera disguised as some familiar object—e.g., a book or pocket watch—for taking pictures unseen by the subject.

See also: *Spy camera; Camera history.*

DEVELOPER IMPROVER. Several organic substances known as developer improvers are sometimes included in the developer either instead of, or in addition to, the restrainer. The chemicals used are benztriazole, 6-nitrobenzimidazole, and 3:5 - dichloro - 2 - amino pyridine. They have very high anti-fogging properties when present in the developer in small quantities—often less than 0·1 per cent.

Developer improvers do not greatly affect the activity or other properties of the developer; they merely keep down fog, including fog caused by lengthy or bad storage of the material.

Developer improvers are sold either in solid form or in solution under various trade names.

DEVELOPERS

A developer converts the invisible latent image formed during exposure into a visible form. It does this by changing into black metallic silver the silver salt compounds in the film or plate that have been affected by light.

Developers are sold either in ready-mixed powder forms or in made-up stock solutions which have only to be dissolved or diluted in water to be ready for use.

Many photographers choose to make up their own developer from one of the multitude of published formulae.

A developer for black-and-white films and papers usually consists of:—

(1) A developing agent: this does the actual work of converting the silver compounds in the sensitive material into a silver image. Some developers use more than one of these agents.

(2) A preservative: this stops the developer from deteriorating too rapidly.

DEVELOPING AGENTS COMPARED

Temperature Coefficient	Inherent Grain	Development Speed (Activity)	Other Characteristics	Remarks
Normal	Normal	Normal	Normal contrast. Will develop even in acid solution or in presence of hypo. Low fog formation	Amidol developers easily give pure blacks on bromide papers. Suitable for any normal developer, but not very popular owing to low keeping qualities
Fairly high	High	Normal	High contrast. Greatly resembles hydroquinone, but is more stable and less sensitive to temperature. Low fog formation	Warm tone developer for chlorobromide papers. Also suitable in any normal developer instead of hydroquinone
High	Normal	Low, except in strongly alkaline solution	Normal to soft gradation. Very low fog formation	Used in warm tone developers and in fine grain formulae. Very suitable for slow development methods as it produces practically no aerial fog
High	High	Faster the more strongly alkaline	High contrast, particularly with caustic soda or potash. High fog formation, hence needs lot of restrainer	Used as high contrast developer with caustic alkalies. Also in warm tone and normal developers
Normal	Low	Low	Fairly low contrast. Low fog formation	Used in fine grain developers. Has some characteristics of both paraphenylene diamine and pyrocatechin
Normal	Normal	High	Very low contrast. Moderate fog formation	Used in low contrast developers. Impurities in metol may cause skin poisoning with some people. Also used in many standard and fine grain formulae. See metol-hydroquinone
Normal	Normal	Normal	Average contrast; depends on relative proportions of metol and hydroquinone. Moderate fog	Mixture of developing agents; forms basis of many popular standard developers. Combines high activity of metol with contrast giving properties of hydroquinone
Normal	Low	Very low	Low contrast. Low fog formation	Used in fine grain developers. Similar to paraphenylene diamine, but does not stain
Normal	Normal	Normal	Low contrast. Low fog formation	Similar in some ways to metol, and used instead of the latter by people sensitive to metol poisoning. Also main constituent of many concentrated one-solution developers
Normal	Very low	Very low	Very low contrast. Moderately low fog	Used in many super-fine grain developers either alone or in combination with another developing agent (glycin, metol, etc.)
Normal	Normal	High	Soft gradation, resembles metol, but can be used in much lower concentrations	Used in combination with hydroquinone in developers of similar characteristics to metol-hydroquinone. Low toxicity and freedom from tendency to cause dermatitis
High	High	High	Fairly high contrast. Stains the image during development. A great deal of control is possible with pyro developers by altering bromide concentration	Traditional dish developer. Also used in pyro-metol developers
Very high	Normal	High	High contrast. Moderate fog formation. Stains and tans the image during development	Used in special tanning developers. Also ingredient of Meritol fine grain developers

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

(3) An alkali: most developing agents are only active in alkaline solution.

(4) A restrainer: this may be included to reduce fog during development.

Some fine-grain developers contain, in addition to the other ingredients, a solvent of silver salts. This is usually potassium thiocyanate or sodium thiosulphate (hypo) which dissolves some of the silver bromide in the emulsion so that the solution acts partially like a physical developer. To some extent the high concentration of sodium sulphite in most fine-grain developers does the same thing.

There are also one or two substances sometimes added which do not affect the characteristics of the developer as such, but help to give clean negatives. These include water softeners like Calgon (sodium hexametaphosphate), developer improvers and wetting agents.

Calgon prevents the formation of a precipitate in a developer solution made with hard water. This precipitate is chemically harmless, but it may settle on the film and stop the developer from reaching the image evenly. This may cause small light spots on the negative.

Developer improvers help to minimize fog. They are added to a developer in extremely small quantities and can be quite additional to the restrainer. They are particularly useful when stale materials are being developed.

Wetting agents are added to developers to ensure uniform wetting of the emulsion. This reduces the risk of white spots due to air bells.

The table above shows only the inherent activity of the developing agent, not how it behaves when made up into a developer.

NEGATIVE DEVELOPERS

Negative developers can be classified as:

(1) Normal contrast developers.
(2) High contrast developers.
(3) Low contrast developers.
(4) Formulae with special characteristics, such as high speed developers, tanning developers, etc.
(5) Various degrees of fine grain formulae.

The properties of any developer depend, however, as much on the relative proportions of the ingredients as on their chemical nature. The chemical process of development is much the same for all developers. The activity and other characteristics can be altered in many cases just as effectively by using more or less of, say, the alkali, as by changing from one alkali to another. Only a small range of chemicals is therefore necessary to produce developers of widely varying characteristics.

Metol-Hydroquinone Developers. The most popular normal negative developer is a combination of metol and hydroquinone, or M.Q. This is the standard formula recommended by most manufacturers of films and plates. M.Q. developers combine the characteristics of metol (high film speed and good gradation) with those of hydroquinone (high density and contrast).

Most M.Q. formula are of the following type:

Metol	8–35 grains	0·5– 2	grams
Sodium sulphite, anhyd.	½–2½ ounces	12–60	grams
Hydroquinone	30–120 grains	2– 8	grams
Sodium carbonate, anhyd.	⅜–1¼ ounces	10–30	grams
Potassium bromide	2–20 grains	0·1– 1	grams
Water to make	40 ounces	1,000	c.cm.

This represents the relative proportion of the ingredients rather than the exact dilution. Usually the developers are made up in the form of more or less concentrated stock solutions which are then diluted about two to five times for dish development, and five to fifteen times for tank development. The development times naturally depend on the concentration as well as on the amount of agitation. The time for medium speed films and normal intermittent agitation is about eight to ten minutes at 65° F. (18·4° C.), with the above concentration.

These proportions are characteristic of many standard developers such as Focal Universal, Ilford ID-2, Kodak D.72, etc.

The normal metol : hydroquinone ratio is 1 : 4. This may be decreased to about 1 : 2 to produce a softer developer.

The usual sodium sulphite proportion does not vary much beyond the limits indicated, but occasionally a little sodium bisulphite or potassium metabisulphite is included.

The alkali concentration varies to a greater extent. It may fall to as low as one-quarter of the value given, though it is rarely higher than 1·5 per cent at normal tank strength. The alkali content greatly influences development time. This accounts to some extent for the wide range of different development times.

Potassium carbonate is sometimes used instead of the sodium salt. The equivalent concentration to produce the same pH at this level is very roughly the same. At high dilutions of the developer seven parts of potassium carbonate produce the same pH as about six parts of sodium carbonate. In their effect on the developer, one is as good as the other, but sodium carbonate is cheaper and more popular.

Sodium metaborate or Kodalk can be used in normal M.Q. developers with the following advantages: the energy of the developer is more easily controlled; there is less likelihood that aluminium carbonate will be precipitated from hardening fixers containing alum; no gas (carbon dioxide) is given off when the developer is neutralized in certain types of stop bath or acid fixer. This is particularly important in hot weather development where the emulsion easily forms blisters in any case.

(Sodium metaborate can also be made by mixing one part sodium hydroxide with about five parts borax, both being dissolved in water. This is equivalent to about seven parts of sodium metaborate.)

Tank strength ...	Above	Above	Above	Half above	Half above	Above	Above	Above	Above	Above	Above	Above	Above

The quantities given represent parts in 1,000 parts of water, i.e., grams per litre.

Caustic alkalis are rarely used in M.Q. developers.

The proportion of potassium bromide remains high to keep fog as low as possible, particularly with certain high speed films and plates. This slows down development, but is otherwise unimportant.

Phenidone-hydroquinone Formulae. As an alternative to metol, phenidone is used in a number of developers. Generally very much smaller quantities of phenidone are needed (around one-tenth of the metol concentration). The resulting developer has characteristics similar to a metol-hydroquinone formula, but has the advantage of not causing dermatitis in people whose skin is allergic to metol.

The phenidone-hydroquinone ratio is normally around 1 : 25 to 1 : 40; the other ingredients have the proportions and concentrations shown for the typical MQ formula above.

A typical negative developer formula (Ilford ID-67) is:—

Sodium sulphite, anhyd.	3	ounces	75	grams
Hydroquinone	140	grains	8	grams
Sodium carbonate, anhyd.	1½	ounces	37·5	grams
Phenidone	4½	grains	0·25	gram
Potassium bromide	35	grains	2	grams
Restrainer solution	290	minims	15	c.cm.
Water to make	40	ounces	1,000	c.cm.
	Phenidone		... ...	...

The restrainer may be a solution containing 1 per cent each of benztriazole and sodium carbonate, or one of the various proprietory restrainer solutions on the market.

Dilution of the above developer is 1 : 2 up to 1 : 5. If the sodium sulphite concentration is reduced to about half and the potassium bromide concentration to about two-thirds, the developer can also be used for printing papers (contact papers at about full strength, enlarging papers diluted 1 : 1) and so becomes a universal developer.

Pyro-Soda Developers. Pyro is one of the traditional developing agents and is still popular with individual workers for developing plates by inspection. It tends to give thin, crisp negatives with excellent contact-printing quality. Unfortunately it also stains fingers and dishes (early photographers could generally be recognized by their blackened finger-nails).

Pyrogallic acid does not keep well in alkaline solutions so it is nearly always made up separately as a stock solution with potassium metabisulphite or sodium bisulphite.

The normal pyro concentration in the working solution is about 0·05–0·1 per cent. Some developers, however, contain up to 0·6 per cent.

The amount of sodium sulphite used varies between about 0·6 and 2·5 per cent. Pyro developers containing little sulphite stain the film yellow.

The alkali is generally sodium or potassium carbonate. Caustic alkalis have also been used, but they increase staining.

The proportion of potassium bromide in most normal formulae is about 0·1–1 gram per litre of working solution (2–20 grains per 40 ounces). Potassium bromide in a pyro developer reduces the effective speed of the negative material and it can be added during dish development by inspection to compensate for over-exposure.

The following is a typical pyro-soda developer formula (Ilford ID-1):

Stock solution A.				
Pyro	88	grains	5	grams
Potassium metabisulphite	22	grains	1·2	grams
Water to make	2	ounces	50	c.cm.
Stock solution B				
Sodium carbonate, anhyd.	¾	ounce	20	grams
Sodium sulphite, anhyd.	1	ounce	25	grams
Potassium bromide	10	grains	0·6	grams
Water to make	20	ounces	500	c.cm.

For dish development take 1 part A, 10 parts B, and 9 parts water. For tank development use only 5 parts B and 14 parts water to 1 part A. The average tank development time is 10–12 minutes at 65° F. (18·4° C.).

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Glycin Developers. Glycin is a slow working developer which keeps very well in solution and is comparatively free from any tendency to aerial fog.

The following is a typical glycin developer formula:

Glycin	1¼ ounces	37 grams
Sodium sulphite, anhyd.	1¼ ounces	30 grams
Potassium carbonate	7 ounces	175 grams
Water to make	40 ounces	1,000 c.cm.

For normal tank development dilute 6 times. Development takes about forty-five minutes at 65° F. (18·4° C.). For stand development dilute about fifty times, and develop for 4–5 hours.

Para-aminophenol Developers. Para-aminophenol is chemically related to metol and has similar characteristics as a developing agent. It is, however, free from any tendency to cause skin poisoning and can therefore be used as a substitute by photographers who are allergic to metol. A typical para-aminophenol hydroquinone developer is Kodak DK-93 :

Para-aminophenol hydrochloride	88 grains	5 grams
Sodium sulphite, anhyd.	1¼ ounces	30 grams
Hydroquinone	44 grains	2·5 grams
Kodalk	350 grains	20 grams
Potassium bromide	9 grains	0·5 grams
Water to make	40 ounces	1,000 c.cm.

Average development time is 10–20 minutes at 65° F. (18·4° C.).

Para-aminophenol is also the developing agent in many commercial highly concentrated developers.

High Contrast Developers. Hydroquinone is the principal developing agent for high contrast. So it is possible to increase the contrast given by a normal M.Q. developer by raising the proportion of hydroquinone to 6 : 1 or even 10 : 1, and using a solution 2-4 times stronger. In addition the bromide content of contrast developers is comparatively high.

Higher alkalinity of the developer also gives increased contrast, so sodium or potassium hydroxide may be used instead of sodium carbonate (about 1/10 the amount).

For even greater contrast hydroquinone is used alone with either sodium (or potassium) carbonate or sodium or potassium hydroxide as an alkali. The hydroquinone and alkali are usually made up in separate solutions and bisulphite or metabisulphite used as a preservative for the hydroquinone solution to give better keeping qualities. The caustic hydroquinone developers often contain a high concentration of potassium bromide (up to 10–12 grams per 1,000 c.cm. or ½ ounce per 40 ounces).

Hydroquinone developers without metol or other agents tend to have a long induction period, and develop the image simultaneously throughout the depth of the emulsion.

Extreme Contrast Developers. For certain graphic arts purposes images of maximum contrast and outline sharpness are required. These are obtained by developing ultra-contrasty films in extreme-contrast developers (usually based on hydroquinone) containing paraformaldehyde. These so-called lith type developers suffer rapid local exhaustion and thus yield special edge effects at boundaries between very bright and very dark image portions.

Exhausted developer from dark image areas diffuses across the boundary and holds back the density of neighbouring light areas. At the same time comparatively unused developer from thin image areas diffuses across to dense areas and develops up the edges of the latter to extra density. This yields an extra sharp

boundary line, as is required for a line or half-tone dot image.

A typical formula is:—

Sodium sulphite, anhyd.	1¼ ounces	30 grams
Paraformaldehyde	130 grains	7·5 grams
Potassium metabisulphite	45 grains	2·6 grams
Boric acid, cryst.	130 grains	7·5 grams
Hydroquinone	400 grains	22·5 grams
Potassium bromide	28 grains	1·6 grams
Water to make	40 ounces	1,000 c.cm.

After making up, this should be allowed to stand for about two hours before use.

Low Contrast Developers. Developers containing only metol or para-aminophenol as developing agent produce images of comparatively low contrast. The composition of the developer is similar to the standard M.Q. formula, but with more metol and without hydroquinone. Metol is more stable in solution and needs less sodium sulphite.

Developers of this kind tend to act as surface developers, i.e., building up the image first on the surface of the emulsion and only then going deeper. This property is useful for minimizing halation and similar effects which occur strongest in the deeper parts of the emulsion.

Kodak DK-15 is similar, but about three times as concentrated. It uses Kodalk instead of sodium carbonate and also contains some sodium sulphate to make it suitable for processing at high temperatures.

Many fine-grain developers give low contrast images.

COMPARISON OF METOL DEVELOPERS

	Ansco 120	*Gevaert G-253*	*Ilford ID-3*	*Ilford ID-15*	*Kodak D-165*
Metol	4·1	1·5	1·5	1·5	1·5
Sodium sulphite, anhyd.	12	10	6·3	10	6·3
Sodium carbonate, anhyd.	9·7	10	9	9	9

Water to make	1,000	1,000	1,000	1,000	1,000

Maximum Energy Developers. This type of developer is intended to bring out the maximum speed of a film or plate, particularly in cases of under-exposure.

Pyro-metol is a maximum energy developer which relies partly on the stain produced by pyrogallic acid to give printing density to the negative, and partly on the ability of the metol to develop an image even in greatly under-exposed regions of the film or plate.

The following is a formula for a pyro-metol developer:

Stock solution A		
Metol	35 grains	2 grams
Potassium metabisulphite (or sodium bisulphite)	70–100 grains	4–6 grams
Pyro	70–100 grains	4–6 grams
Water to make	20 ounces	500 c.cm.
Stock solution B		
Sodium carbonate, anhyd.	1½ ounces	37 grams
Water to make	20 ounces	500 c.cm.

For use take equal parts of A and B. Average development time is 6–8 minutes at 65° F. (18·4° C.).

Caustic metol-hydroquinone is a completely different type of high energy developer. This contains a high concentration of metol and hydroquinone (dissolved with the help of alcohol if necessary) and sodium hydroxide.

The following is the formula for a maximum energy developer:

Wood alcohol	2 ounces	50 c.cm.
Metol	240 grains	14 grams
Sodium sulphite, anhyd.	2 ounces	50 grams
Hydroquinone	240 grains	14 grams
Sodium hydroxide	160 grains	9 grams
Potassium bromide	160 grains	9 grams
Water to make	40 ounces	1,000 c.cm.

Development takes about 4–8 minutes at 65° F. (18·4° C.). The mixed developer hardly keeps at all.

If the sodium hydroxide is doubled, the development time can be reduced to about one minute. Some of the rapid developers are of the high energy type to utilize the maximum film speed.

The effective film speed is also increased by adding a small amount of hydrazine or its derivatives to the developer, with an anti-fogging agent. Such an energizing solution recommended by Kodak is :

Hydrazine dihydrochloride	100 grains	5·3 grams
6-nitrobenzimidazole nitrate (0·2%)	2¾ ounces	67 c.cm.
Water to make	4 ounces	100 c.cm.

Three parts of this are added to about one hundred parts of a standard M.Q. developer. The developer and energizer mixture does not keep.

Concentrated Developers. Some developers can be made up very conveniently in strong stock solutions and diluted some twenty to sixty times for use.

All these formulae are based on para-aminophenol with potassium metabisulphite as preservative, and enough sodium hydroxide to bring them into solution.

A typical formula for a concentrated developer is:

Para-aminophenol (free base)	4 ounces	100 grams
Potassium metabisulphite	12 ounces	300 grams
Water	20 ounces	500 c.cm.

These ingredients are brought into solution with the least amount of concentrated sodium or potassium hydroxide solution and then made up to the final volume of 1,000 c.c. (40 ounces).

For normal tank development the solution is diluted about forty times. Development takes about fifteen to twenty minutes at 65° F. (18·4°C.).

The same principle works with metol-hydroquinone but not to such high concentration. A suitable formula is:

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Wood alcohol	2 ounces	50 c.cm.
Potassium metabisulphite	35 grains	2 grams
Metol	¾ ounces	19 grams
Hydroquinone	1½ ounces	38 grams
Potassium metabisulphite	7 ounces	175 grams
Potassium bromide	160 grains	9 grams
Water to make	40 ounces	1,000 c.cm.

The potassium metabisulphite is dissolved in two lots. When the second lot has been dissolved as far as possible, just enough 50 per cent sodium or potassium hydroxide solution is added to dissolve all the precipitate in the solution. The bromide is then added, and the solution made up to the final volume.

For normal tank development this is diluted about twenty times.

Replenishers. Many developers can be used repeatedly but as each film takes some strength out of the solution subsequent development times have to be increased.

A better way of re-using developers is to replace some of the chemicals used up during development in the form of a replenisher.

The simplest replenisher would be concentrated developer stock solution, but all the ingredients of a developer are not used up at the same rate. The concentration of the developing agents and of the alkali decreases fairly rapidly whereas the potassium bromide content increases slightly. So a suitable replenisher is not identical with the developer; it contains the chemicals in the correct proportion to compensate for real losses during development. In use, about 15–25 c.cm. (½–1 ounce) of replenisher solution are added to 1,000 c.cm. (40 ounces) of developer working solution for each film developed. If this increases the solution volume too much, some of the old developer is poured off first.

Usually the composition of replenishers is:

Developing agents: about 1½–2 times the concentration in the working developer.

Sodium sulphite: same concentration as in the developer.

Alkali: with alkalis like borax or metaborate, the replenisher will contain about 5–10 times as much as the developer. With carbonate alkalis the replenisher contains about 2–4 times as much as the working developer. Caustic soda or potash is also commonly used.

Restrainer: the majority of replenishers add no potassium bromide.

Other additions: neither developer improvers nor wetting agents are required in the replenisher. Solvent fine grain developer replenishers usually contain up to three times as much potassium thiocyanate or hypo as the developer itself.

Replenishers are only worth while with developers which keep well in solution. By using a replenisher, 1,000 c.cm. (40 ounces) of developer can be used for about twenty or more films. But pyro formulae and developers containing caustic soda as alkali deteriorate much too rapidly to justify replenishment.

There is no point in using a replenisher with dilute tank developers, nor with developing tanks which take less than about 400 c.cm. (15–16 ounces) of solution to develop one film. Under these conditions the developer is so exhausted after use that it is best thrown away.

Replenishers are best used in fairly concentrated solution (such as most fine-grain formulae) where it would be comparatively expensive to use fresh developer solution for each film.

High-speed Developers. Concentrated and highly alkaline developers will bring development times down to about ½–1 minute. They are usually derived from contrast developers of the metol-hydroquinone or caustic hydroquinone types which are already highly alkaline. With such strong solutions potassium bromide is usually not efficient enough to keep down fog, so a 0·1 per cent solution of phenosafranine is often added.

The presence of any salts not directly engaged in the development process slows down the development, so the amount of sodium sulphite is kept very low. In consequence these developers do not keep at all once they are mixed.

Such a developer may, for instance, be:

Sodium sulphite, anhydrous	52 grains	3 grams
Hydroquinone	52 grains	3 grams
Phenosafranin, 0·1 per cent	38 minims	2 c.cm.
Water to make	2 ounces	50 c.cm.

Just before use add an equal volume of 12 per cent sodium hydroxide solution.

A 10 per cent acetic acid stop bath is advisable immediately after development (which takes about forty-five seconds), followed by a rapid fixer.

Two bath methods of high speed development rely on very concentrated developing agents, followed by a short immersion in a caustic alkali solution. The following is a suitable formula:

Hydroquinone	2 ounces	50 grams
Sulphurous acid, 8 per cent solution	10 ounces	250 c.cm.
Phenosafranin, 0·1 per cent solution	¾ ounce	20 c.cm.
Water to make	40 ounces	1,000 c.cm.

The film or plate is immersed in the solution for 5–10 seconds and then given 3 seconds in a 30 per cent solution of sodium or potassium hydroxide, with 1 part formalin solution added to every 40 parts of alkali solution. Again a stop bath and rapid fixer should be used.

At high temperatures (up to 85° F. or 30° C.), development is complete after about 4–5 seconds in the developer, followed by 1–2 seconds in the alkali bath. There is little danger of damage to the emulsion from the high temperature and alkalinity of the solution (particularly if formalin is present in the second bath) because the emulsion has no time to swell appreciably.

After the high speed fixing bath the emulsion

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

is washed in running water for 30 seconds, and sandwiched in glycerine between two glass plates. It can then be enlarged immediately, and rewashed and dried normally later on.

Prints can be processed at high speed in much the same way. After the final 30-second wash they can be dried in front of a radiator or fire in about 30 seconds.

Tanning Developers. Certain developers tan the gelatin during development of the silver image. The degree of tanning (which hardens the gelatin and renders it insoluble) is proportional to the density of the silver deposit produced.

Most developing agents will, under suitable conditions, tan the gelatin. The effect is greatest with the polyhydroxy-benzenes, especially with pyrocatechin and pyrogallic acid.

One of the essentials of such a tanning developer is a low sulphite content, otherwise the tanning effect is largely lost. A fairly high alkalinity, and sometimes the addition of substances like alcohol, improve the tanning action. This is due to the polymerization of the oxidation products of the developing agent (quinone and quinone-like compounds) which are formed in the gelatin layer during development.

Tanning developers are employed for making gelatin matrices, i.e., images of hardened gelatin. These matrices are used in various processes—e.g., dye transfer and imbibition colour print processes, and photomechanical processes such as photolithography. Tanning developers are also sometimes used for controlling excessive contrast; where the emulsion has received most exposure, the increased tanning of the gelatin in those areas tends to retard development.

A typical tanning developer using pyrocatechin is:

Pyrocatechin	35 grains	2 grams
Sodium sulphite, 1 per cent solution	1 ounce	25 c.cm.
Sodium hydroxide, 1 per cent solution	2 ounces	50 c.cm.
Water to make	40 ounces	1,000 c.cm.

Average development time is 15-20 minutes at 65° F. (18·4° C.).

This developer must be made up immediately before use. Neither the sulphite nor the sodium hydroxide solutions keep well at this dilution, but are more convenient to measure when made up in this way.

A formula using pyrogallic acid is:

Stock solution A		
Pyrogallic acid	70 grains	4 grams
Sodium sulphite, anhydrous	175 grains	10 grams
Water to make	40 ounces	1,000 c.cm.
Stock solution B		
Sodium carbonate, anhydrous	485 grains	28 grams
Water to make	40 ounces	1,000 c.cm.

Equal parts of A and B are mixed immediately before use. Average development time is 6-10 minutes at 65° F. (18·4° C.).

A developer of this type using hydroquinone can be obtained by making up a standard caustic hydroquinone developer, but reducing the sulphite or metabisulphite content to about 10-20 per cent of the normal amount.

After development the unhardened gelatin can be washed out with warm water, leaving the tanned relief image. The silver image itself can also be bleached out either by a normal bleacher or by a tanning bleacher which further hardens the gelatin. The use of such a tanning bleacher before the removal of the unhardened gelatin will increase the contrast.

FINE GRAIN NEGATIVE DEVELOPERS

During normal development the image-forming silver in the sensitive emulsion tends to clump into comparatively large grains. These become unpleasantly obvious when the negative is sufficiently enlarged. Fine grain developers counteract this clumping tendency in three principal ways. There are thus three types of fine grain developer: normal developer, low energy developer and solvent developer.
